The chest radiograph has a high diagnostic accuracy for detecting radioopaque tubes and devices inserted in the critically ill patient, but only a moderate accuracy in detecting various cardiopulmonary abnormalities and pinpointing their exact etiology.[1] Despite this limitation, the chest radiograph serves as a vital and objective adjunct to the bedside physical examination in the rapidly changing clinical course of critically ill patients.

The current widespread use of chest radiography in the Intensive Care Unit (ICU) is based on studies that have shown that daily films in the ICU often reveal significant and/or unsuspected abnormalities in 34 to 65% cases that may change the patient's diagnosis or management.[2-4] For example, in a review of 1,354 Chest X-ray (CXR) studies on 167 patients in the ICU, Bekemeyer et al.[2] reported an incidence of 34.5% of new or increased abnormalities, or tube or catheter malposition. Excluding catheter malposition adjustments, as many as 28.5% of the CXR studies led to a change in the diagnostic approach or therapeutic interventions. More recent studies have arrived at a different conclusion, reporting that only 1.9 to 13.3% of daily routine CXRs in the ICU lead to a change in clinical management.[5-7] Ordering a CXR only when clinically indicated rather than on a daily routine basis translated into significant cost savings without adversely affecting ICU length of stay or mortality.[5,6]

Assimilating the somewhat contradictory findings of different studies, the consensus opinion of the American College of Radiology (ACR) Expert Panel, revised as of 2008, recommends that routine daily radiographs are indicated for ICU patients with acute cardiopulmonary problems, including those on mechanical ventilation. Stable patients admitted for cardiac monitoring, or in stable patients admitted for extrathoracic disease only, an initial admission radiograph is recommended, with follow-up radiographs obtained only for specific clinical indications. Patients who require cardiac monitoring but are otherwise stable require only an initial admission film. Additional radiographs are indicated only when a new device is placed or when there is a specific question regarding cardiopulmonary status.

The advent of computed radiology has given us the ability to acquire, store and transmit chest radiographs in digital format, as well as view images on computers using Picture Archiving and Communication Systems (PACS), thereby cementing the role of chest radiology in the ICU setting. Nevertheless, the utility of chest radiography in the ICU goes hand-in-hand with important pitfalls in interpretation. The standard postero-anterior (PA) chest radiograph is rarely feasible in the ICU patient and is usually substituted by an Antero-Posterior (AP) film, often in a supine or semi-recumbent position, with varying degrees of inspiratory effort. This technique renders a magnified view of the heart and mediastinum, diverts blood to the lung apices, allows pleural effusions to layer and disguise themselves as airspace opacities, and renders small pneumothoraces, all but invisible.[8]

A suboptimal inspiratory effort can create a spectrum of illusions ranging from basilar atelectasis to pulmonary edema. Compounding this picture is often an array of wires and tubes as well as varying folds of subcutaneous and breast tissue. The well-trained intensivist must learn to walk the fine line between detecting subtle yet important findings and dismissing potential artifacts. Having a strong clinical suspicion for expected problems, investing the time to compare with previous films and ordering a repeat film with a different technique or position, when necessary, can often save the day. In the ensuing sections, we will briefly discuss commonly encountered patterns of disease on plain chest radiography in the critical care setting.

Cardiopulmonary Imaging

The radiological findings in cardiac as well as pulmonary parenchymal diseases are often nonspecific, underscoring the importance of clinical correlation.

Pneumonia

Radiographically, pneumonia presents as air-space opacities, which may be hazy (as in *Pneumocystis jiroveci* or viral pneumonia (Fig. 145.1) or dense (as in bacterial pneumonia). The opacities may be focal or diffuse, or may be concealed in the retrocardiac area. The opacities may silhouette the right heart border, suggesting involvement of the right middle lobe. Pneumonia may affect gravity-dependent portions of the lung and have air bronchograms mimicking Acute Respiratory Distress Syndrome (ARDS) and atelectasis. Although, pleural effusions can be differentiated from pneumonia by the lack of air bronchograms and the presence of the meniscus sign, they often coexist with pneumonia and may indeed suggest the progression to complicated parapneumonic effusions or empyema. The importance of clinical correlation, such as the persistence of fever and pleuritic chest pain, cannot be stressed enough in this setting.

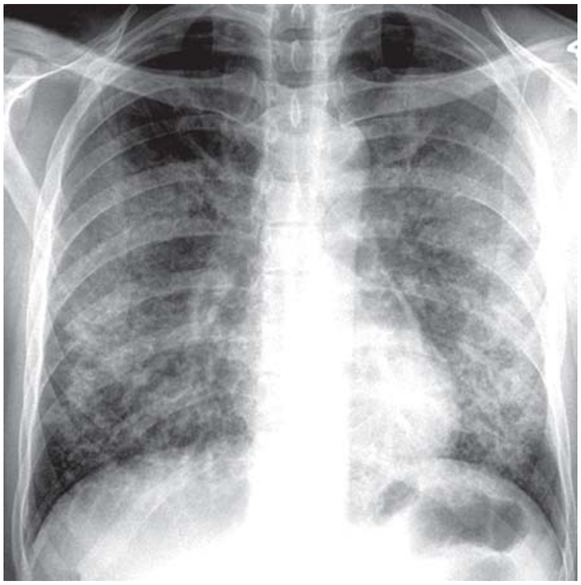

Fig. 145.1: *Pneumocystis jiroveci* – diffuse bilateral alveolar opacities in a 45 years old woman with HIV

Other radiographic patterns associated with pneumonia include the formation of cavities (as in necrotizing pneumonia from *Staphylococcus aureus* bearing the Panton Valentine Leukocidin gene), cavities in the upper lobes (as in pulmonary tuberculosis) and the development of bronchopleural fistulas. Finally, the appearance of a new opacity suggestive of pneumonia after 72 hours of mechanical ventilation, in conjunction with clinical and microbiological data, confers the diagnosis of ventilator-associated pneumonia (VAP).

Atelectasis

Atelectasis results from mucus plugging and secretions, concomitantly with a difficulty in clearing secretions. This may result from general anesthesia, sedation, neuromuscular blockade or postoperative pain causing splinting. Minimal basal subsegmental or discoid atelectasis appears as linear streaks and is quite common in the ICU patient but of no major physiological significance. More extensive atelectasis, varying from total lung collapse to subsegmental collapse, may cause or worsen hypoxemia. Although, atelectasis can disguise itself as pneumonia with the presence of air bronchograms and fever, there are some important distinguishing clues. Loss of volume on the side of a parenchymal opacity, with crowding of the vasculature, elevation of the ipsilateral hemidiaphragm or ipsilateral shift of the mediastinum, suggests atelectasis.

The rapid appearance of a parenchymal opacity as well as disappearance on a subsequent film after adequate pulmonary toilet is an indicator of atelectasis. In the setting of surgical ICU, atelectasis is often caused by splinting from pain following surgery. Radiographic resolution can often be seen following ambulation, chest physical therapy and incentive spirometry. Atelectasis occurs in the left lower lobe in 66% cases, right lower lobe in 22% cases and right upper lobe in 11% cases.[9] Compression of the left lower lobe by the heart in the supine patient, combined with relative difficulty of blindly inserting a suction catheter into the left lung, is thought to account for the increased predisposition of atelectasis of the left lower lobe atelectasis.[10]

Collapsed lung segments and lobes follow well-recognized anatomical pathways, unlike other causes of air-space diseases such as pneumonia or ARDS. The

TABLE 145.1: Radiographic appearance of atelectatic lung segments

Atelectatic segment	Radiographic appearance
Right upper lobe	The right upper lobe collapses into a triangular opacity, with the lesser fissure migrating toward the anterior, superior and medial portion of the chest.
Right middle lobe	Loss of definition (silhouetting) of the right heart border. (similar to pneumonia affecting the right middle lobe)
Right lower lobe	The collapsed lobe moves centrally and inferiorly towards the lower thoracic spine, where it is seen as a triangular opacity. Silhouetting of the right hemidiaphragm and air bronchograms are often seen. The minor fissure may show some inferior displacement. Right-lower-lobe atelectasis can be differentiated from right–middle-lobe atelectasis by the persistence of the right heart border.
Left upper lobe	Left-upper-lobe atelectasis appears differently than right–upper-lobe atelectasis because the left lung lacks a minor fissure. The collapsed left upper lobe moves anteriorly, with loss of the left upper cardiac border. The left lower lobe expands and migrates superior and posterior to the left upper lobe. The left main bronchus rotates to a nearly horizontal position. There is “veil-like” or hazy opacification of the left hilum, elevation of the left hilum, and aerated lung abutting the arch of the aorta, between the mediastinum and the collapsed left upper lobe (Luftsichel or air crescent sign)
Left lower lobe	The left lower lobe collapses medially and posteriorly to lie behind the heart. It classically displays a dense triangular opacity visible through the cardiac shadow, often giving the heart an unusually straight lateral border. Silhouetting of the left hemidiaphragm and air bronchograms are also seen.

intensivist must familiarize himself with these anatomical patterns as outlined in Table 145.1.[10]

Aspiration Syndromes

Impaired consciousness from disease or sedatives, ineffective cough from neuromuscular blockade or critical care neuropathy or myopathy, the placement of endotracheal and nasogastric feeding tubes, as well as inadequate elevation of the head of the bed, all contribute to the development of aspiration syndromes in the critically ill patient. The intensity of resulting pulmonary inflammation is related to the amount of fluid aspirated as well as its pH.

The most commonly aspirated fluid is gastric content (Mendelson’s syndrome). Aspiration of this fluid, with a pH <2.5, causes severe bronchospasm within minutes,[11] followed later by fever and leukocytosis. Chest radiographs usually show progressive opacities in the perihilar and basilar regions in the first 24 hours. In the subsequent 24 to 48 hours there is stabilization of these opacities and usually by 48 to 72 hours there is some evidence of clearing. In up to 25% of patients, this chemical pneumonitis is complicated by bacterial infection, which should be suspected when the radiographic opacities fail to clear in 3 to 7 days.

Pulmonary Edema

The accumulation of fluid in the lung interstitium or alveolar space, generally referred to as pulmonary edema, is a common occurrence in the critically ill patient. The etiology may be increased hydrostatic pressure, as seen in Congestive Heart Failure (CHF), renal failure and fluid overload; or increased permeability of the pulmonary capillaries, as seen in ARDS, inhaled irritants, near-drowning, altitude sickness, transfusion reactions, etc. These two distinct types are often referred to as cardiogenic and non-cardiogenic pulmonary edema respectively. Milne et al[12] in a classic study of 216 CXRs, found 91% accuracy in differentiating capillary permeability edema (e.g. ARDS) from other varieties (Table 145.2).

Several subsequent studies attempted to correlate the degree of CHF, as estimated by Pulmonary Artery Occlusion Pressure (PAOP) or Left Ventricular End-Diastolic Pressure (LVEDP), with CXR findings—the results were generally disappointing.[13,14] One exception is the Vascular Pedicle Width (VPW), described by Milne et al.[12,15], which continues to be studied as a radiologic aid in assessing the patient’s volume status (Fig. 145.2). The VPW is measured by dropping a perpendicular line from the point at which the left subclavian artery exits the aortic arch and measuring across to the point at which the superior vena cava crosses the right main stem bronchus. When the right border of the pedicle is indistinct, the vertical lateral border of the superior vena cava or right brachiocephalic vein has been used in VPW measurements.[16] Factors that might influence VPW measurements include; VPW varies with patient height and body build, VPW measured with the patient in a

TABLE 145.2: Cardiogenic vs. Non-cardiogenic pulmonary edema

Features	*Cardiogenic*	*Non-cardiogenic*
Causes	Eg. CHF	Eg. ARDS
Pathogenesis	Increased hydrostatic pressure	Increased capillary permeability
Cardiac shadow	Enlarged	Normal in size
Distribution of opacities	Basal predominant opacity, even from chest wall to heart, with perihilar component (“bat wing” appearance)	Patchy, peripheral opacity sparing the costophrenic angles
Pulmonary blood flow distribution	Upper lobe vessels larger compared to lower lobe vessels	Normal or balanced
Peribronchial cuffing	Very common	Not common
Pleural effusions	Very common	Not common
Air bronchograms	Not common	Very common
Septal lines	May be present	Not usually present
Vascular pedicle width on CXR shot in upright position	Enlarged (>53 mm)	Reduced (<43 mm)

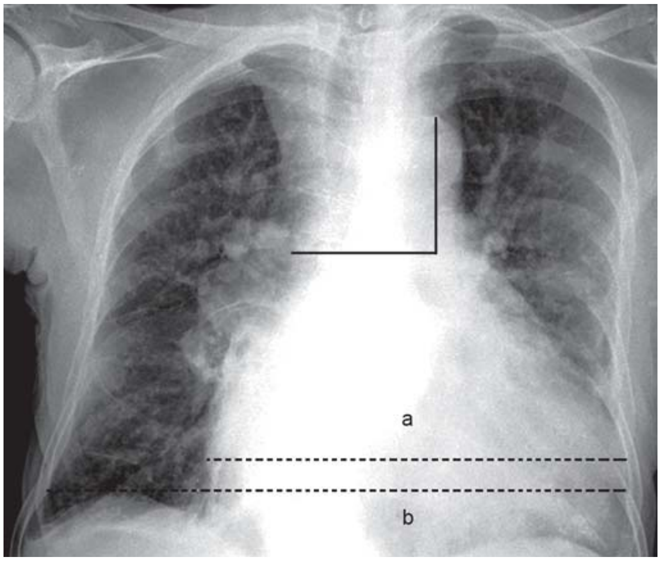

Fig. 145.2: Congestive heart failure. A 65 years old woman admitted with shortness of breath. The vascular pedicle width (VPW), (see solid lines), measured by dropping a perpendicular line from the point at which the left subclavian artery exits the aortic arch and measuring across to the point at which the superior vena cava crosses the right main stem bronchus, is 75 mm in this case. (A value >70 mm is strongly suggestive of volume overload.) The cardiothoracic ratio, measured as the ratio of the largest transverse cardiac diameter (see dotted line) to the largest transverse thoracic diameter (a/b), is also increased. (A value >0.55 suggests cardiomegaly)

supine posture is approximately 17% greater than that with the patient in an upright position, the rotation of the patient to the right (i.e. a left anterior oblique projection) increases VPW, whereas the rotation of the patient to the left (i.e. a right anterior oblique projection) decreases the VPW. ICU CXRs should therefore be taken in a reproducible fashion, with similar body positioning and focal film distance (40 inches from the chest wall), widening of the VPW is a normal postoperative CXR finding following cardiac transplantation.[16]

In a prospective study of 33 mechanically ventilated ICU patients with supine AP CXRs, there was a significant correlation between the PAOP and the VPW, ($r = 0.45$, $p = 0.0076$) and the cardiothoracic ratio (CTR, calculated by dividing the maximum cardiac width by the maximum thoracic width) ($r = 0.52$, $p = 0.0016$), as well as between the VPW and CTR ($r = 0.49$, $p = 0.0032$).[17,18] In a subsequent prospective study of 100 patients (all of whom had volume status assessed by pulmonary artery catheters), it was found that patients with a VPW of >70 mm coupled with a CTR of >0.55 were more than three times more likely to have a PAOP >18 mm Hg than were patients without these radiographic findings.[18] It has also been reported that an increase in VPW of 5 mm corresponds to an increase in 1 liter of total blood volume in upright, nonmechanically ventilated patients,[19] a widening of the VPW on serial CXRs precedes the development of pulmonary edema in burn patients receiving fluid resuscitation.[20]

VPW decreases significantly with fluid removal during hemodialysis[21] and a decrease in VPW also correlates with the volume of diuresis after recovery from acute lung injury.[22] It appears, therefore, that serial measurements of VPW can give crucial and reliable

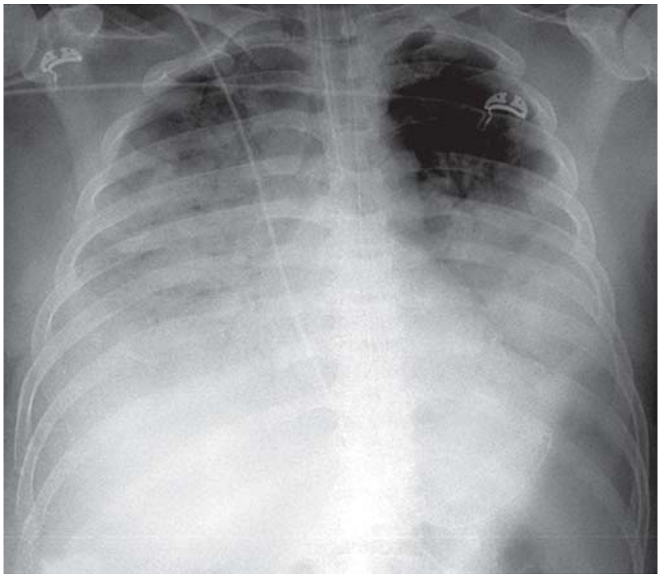

Fig. 145.3: ARDS in a 50 year old male who was found to have H1N1 Influenza. Note the dense bilateral opacities with air bronchograms

information regarding the ever-changing volume status in critically ill patients. Nevertheless, this simple technique unfortunately remains underreported and underutilized.

Acute Respiratory Distress Syndrome (ARDS)

The acute onset of bilateral opacities on the CXR, along with a PaO_2/FIO_2 ratio <200, in the absence of clinical CHF, defines the presence of ARDS. Pulmonary as well as nonpulmonary sepsis, aspiration, blood transfusions and trauma are just some of the many causes of ARDS. ARDS is the final common pathway of lung injury regardless of the etiology and is characterized by damage to the alveolar capillary endothelium, increased vascular permeability, and subsequent development of interstitial followed by alveolar pulmonary edema.

Differentiation between ARDS versus CHF can be difficult; several radiographic clues are listed in Table 145.2. The chest radiographs may be normal in the first 12 hours of development of ARDS. Subsequently, diffuse, ill-defined alveolar opacities appear which may progress to a complete white-out of the lungs (Fig. 145.3). The radiographic phases of ARDS are presented in Table 145.3.[23]

Evaluation of Lines, Tubes and Devices

A plethora of invasive tubes and devices have now become routine in the management of critically ill patients. The CXR has assumed a crucial role in ascertaining the correct positioning of these devices as well as in detecting complications related to their placement. The intensivist must insist on obtaining a CXR promptly after the placement of these devices and should be skilled in their interpretation. Furthermore, while reviewing CXR films in the ICU, it is advisable to develop the habit of identifying all placed devices first before looking for cardiopulmonary disorders.

TABLE 145.3: Radiographic phases of ARDS

Phase	*Radiographic features*
Acute phase (0-12 hours)	Radiograph often normal
Acute phase (12-24 hours)	Diffuse, bilateral patchy alveolar opacities present. Air bronchograms present, pleural effusions are uncommon.
Subacute phase (5-10 days)	With progressive lung destruction, there is transition from alveolar to interstitial opacities. A frequent complication is barotrauma (pneumothorax, pneumomediastinum, pneumoatceles)
Chronic phase (2-3 weeks)	Lung fibrosis and destruction manifested on chest radiography by fibrosis and focal emphysema.

Endotracheal Tube

Endotracheal tubes (ETT) are used to secure airway access in critically ill patients and allow mechanical ventilation. Unfortunately, these tubes are malpositioned

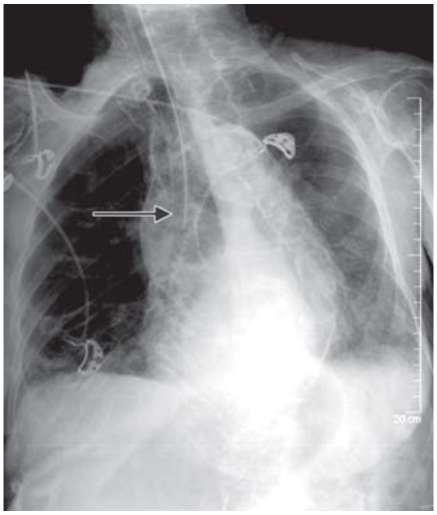

Fig. 145.4: Right mainstem intubation. The endotracheal tube has passed the carina and slipped into the right main bronchus (see arrow). Note the hyperlucency in the overinflated right lung and the diffuse haziness in the non-ventilated left lung

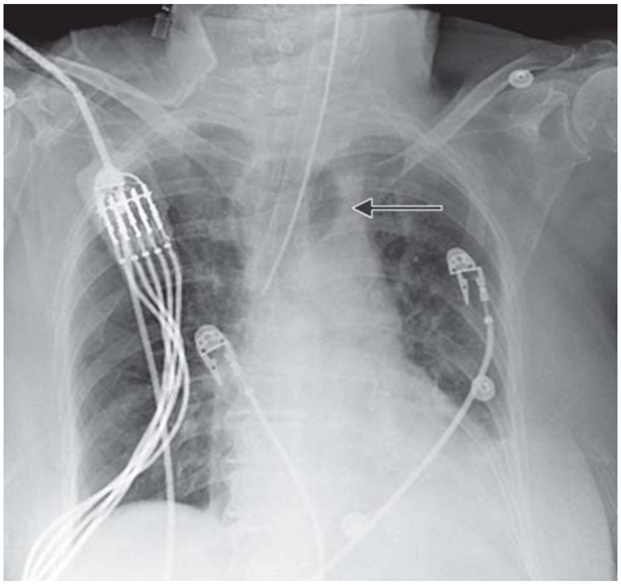

Fig. 145.5: Overinflated cuff of the endotracheal tube. The ratio of the diameter of the cuff and the trachea should be 1:1. In this case, the ratio is 2:1

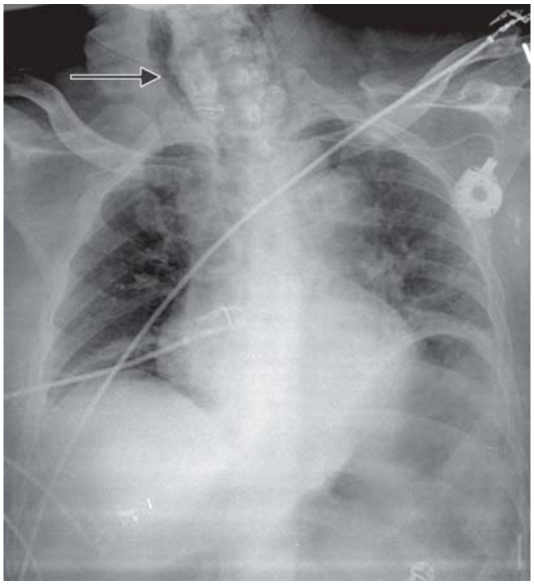

Fig. 145.6: Subcutaneous emphysema. The patient developed cervical esophageal injury during attempted intubation prior to general anesthesia. The surgery was postponed, the patient complained of throat pain and odynophagia in the recovery unit. Note the presence of hypolucent shadows suggestive of air in the soft tissues of the neck. (see arrow)

in about 10% cases[24] (Fig. 145.4). Therefore, all intubated patients should have a CXR immediately post-intubation to confirm the correct position of the ETT. The ideal position of the ETT is in the mid-trachea, 5 to 7 cm above the carina, with the head in the neutral position. The inflated cuff of the ETT should fill the tracheal lumen but not bulge its walls (Fig. 145.5). An overinflated ETT cuff can compromise capillary blood flow in the tracheal mucosa, resulting in tracheal injury and eventually tracheal stenosis.

A difficult intubation should raise the suspicion of tracheal, laryngeal or cervical esophageal perforation, which would manifest on the CXR as subcutaneous emphysema in the neck, pneumothorax or pneumomediastinum (Figs 145.6 and 145.7). Esophageal intubation is suggested by the ETT appearing lateral to the tracheal air shadow.

ETTs also have a tendency to migrate and potentially jeopardize the airway, so, daily CXRs are recommended in all intubated patients to ascertain the correct position of the ETT. It is important to remember that flexion of the head allows the ETT tip to migrate approximately 2 cm distally and therefore, an ETT tip too close to the carina could potentially slip into the right main bronchus. Likewise, extension of the head allows the ETT to migrate approximately 2 cm proximally and therefore an ETT tip too far proximal to the carina could potentially slip out above the vocal cords. Poor chest X-ray exposure may

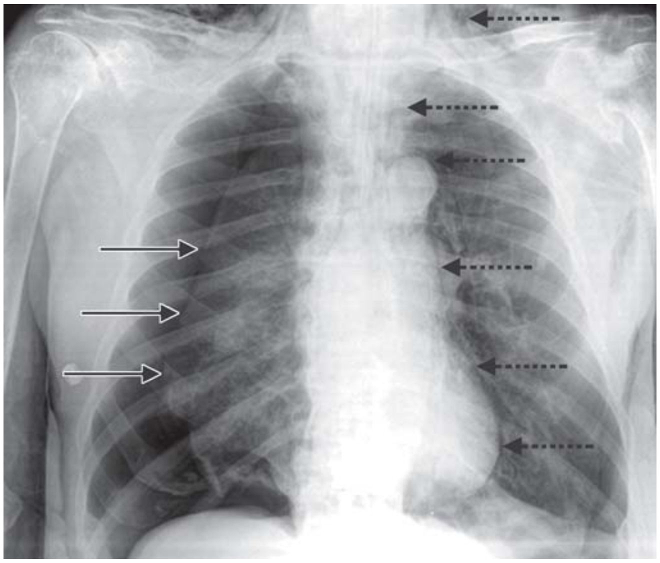

Fig. 145.7: Right pneumothorax+ pneumomediastinum following traumatic intubation with tracheal injury. The right lung has collapsed (see solid arrows pointing at right pleural margin). There is a thin margin of air adjacent the left heat border extending above the aortic knob (see dotted arrows). Also note the subcutaneous emphysema – the fibers of the left pectoralis major muscle are highlighted by shadows of air. The soft tissues of the neck also show hypolucent areas suggestive of air

sometimes not allow recognition of the carina. If a previous radiograph is available, anatomical landmarks may be used to estimate the position of the carina.

Tracheostomy Tube

The tracheostomy tube is initially sutured in place after insertion and is subsequently held in place with a neck strap. Consequently, it does not have the same potential to migrate as the ETT and it typically does not change position with neck flexion or extension. The tip of the tracheostomy tube should again lie well above the level of the carina, usually at the level of the T3 vertebra. Once appropriate placement is confirmed via CXR or bronchoscopy, daily CXRs are not required to confirm the position of the tracheostomy tube.

Nasogastric Tube

Nasogastric Tubes (NGTs) are commonly placed in the ICU for nutritional support or gastric decompression. It is advisable to confirm the placement of every NGT by a CXR prior to use, as an NGT inadvertently inserted into the tracheobronchial tree can deliver enteral feeds to the lungs leading to catastrophic pneumonitis and pneumonia (Fig. 145.8). The tip of the NGT should be visualized beyond the gastroesophageal junction, inferior to the level of the left hemidiaphragm. An NGT sitting at the gastroesophageal junction or in the distal esophagus should be advanced in further to prevent aspiration. Once placement is confirmed and the tube is securely fastened, daily CXRs are not required to confirm position unless migration is suspected.

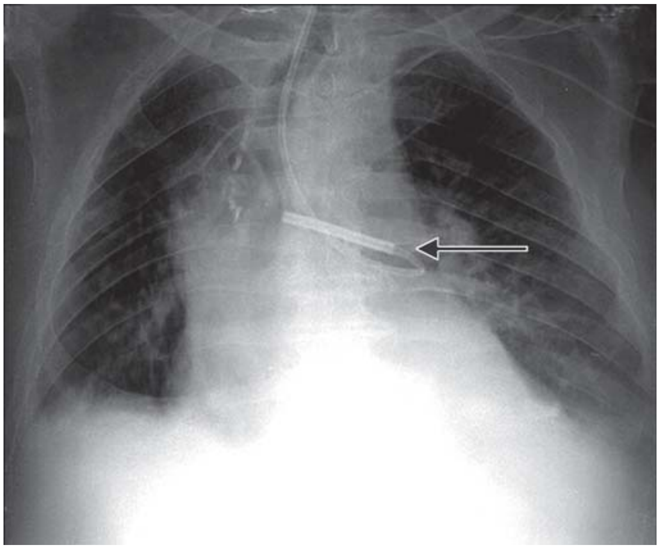

Fig. 145.8: Nasogastric-tube malposition in left mainstem bronchus

Central Venous Catheter

Central venous catheters, inserted via the internal jugular or subclavian vein, are routinely used in the modern ICU for administration of fluids and vasopressors, as well as to monitor the central venous pressure in patients with shock. Again, the intensivist must insist on obtaining a CXR promptly after the placement of a central venous catheter, to confirm its appropriate placement and evaluate for any complications. The catheter tip should ideally lie in the superior vena cava between the right atrium and the most proximal venous valves. The proximal venous valves are usually located 2.5 cm distal to the junction where the subclavian and jugular veins meet to form the brachiocephalic vein. On the CXR, this position usually lies at the anterior part of the first rib, as many as one third of central venous catheters are malpositioned at the time of insertion.[25] These include the subclavian catheter going up the ipsilateral internal jugular vein, contralateral brachiocephalic vein, right atrium, right ventricle, inferior vena cava and hepatic veins, as well as the pleural space. A catheter tip lying in the right atrium or ventricle could induce cardiac arrhythmias by irritating the myocardium.

Pneumothorax is a very well described complication of central venous catheter placement. In a mechanically ventilated patient, a pneumothorax caused during catheter placement could rapidly expand leading to respiratory and hemodynamic compromise. Infusion of fluids and parenteral nutrition formulae into the pleural space via malpositioned catheters have been described, leading to rapidly accumulating pleural effusions with abnormally high glucose or lipid levels.

Pulmonary Artery Catheter

The right heart catheter, which is also referred to as the pulmonary artery catheter, nowadays used primarily to evaluate pulmonary arterial hypertension and to guide vasopressor therapy in patients with combined septic and cardiogenic shock. The catheter is floated to the pulmonary artery via the right ventricle and is usually wedged 5 to 8 cm distal to the bifurcation of the main pulmonary artery. The tip of the catheter should lie within the mediastinal shadow or no more than 3 cm away from the midline on a CXR.[26] A prompt CXR to confirm proper placement and exclude complications such as pneumothorax is a prudent approach. Subsequent daily reconfirmation of proper placement and exclusion of catheter migration can be accomplished by clinical criteria, with a CXR performed only if migration or complication is suspected.

Appropriate clinical criteria used to exclude catheter migration are as follows:

a. Amount of air required to obtain a pulmonary capillary wedge pressure tracing, 1.25 to 1.5 ml (normal) versus less than 1.25 ml (abnormal). When less than 1 ml of air is required to obtain a pulmonary capillary wedge pressure tracing, the balloon should be deflated and the catheter pulled back regardless of the findings on a chest radiograph.
b. Centimeter marking of the pulmonary artery catheter at the introducer hub: 1 cm or less migration in or out from the initial position (normal) versus more than 1 cm migration (abnormal).[26] Locking the hub in place after catheter placement and periodically noting the centimeter marking at the hub are therefore crucially important.

Complications of right heart catheter include rupture of the pulmonary artery and pulmonary infarction, both of which could manifest with hemoptysis and rapidly appearing infiltrates on the CXR. Pneumothorax can occur during placement, as with central venous catheters.

Intra-Aortic Balloon Counterpulsation or Pump (IABP)

The IABP is a device used to augment cardiac function and coronary perfusion in the setting of cardiogenic shock. The device is inserted percutaneously via the femoral artery, and the tip of the balloon should come to lie in the proximal descending thoracic aorta, 2 to 3 cm distal to the origin of the Left Subclavian Artery (LSCA).[27-29] The balloon is distended in diastole, causing increased pressure in the proximal aorta, thus improving coronary artery perfusion, increased oxygenation of the myocardium and improved cardiac output. The balloon is subsequently deflated during systole, thereby decreasing cardiac afterload, left ventricular work and oxygen requirements.

The tip of the device is radioopaque, which facilitates visualization on CXR to confirm proper placement. If positioned too proximal in the arch of the aorta, the balloon can enter the left subclavian artery and become a source of embolism to the brain via the vertebral artery. If positioned too distal in the descending thoracic aorta, the balloon can potentially block the ostia of the renal or superior mesenteric arteries, causing catastrophic end-organ damage. On CXR, the recommended position for the tip of the balloon is at the inferior aspect of the "aortic knob",[30] which is a radiographic term, not an anatomic one. The "aortic knob" is opacity on the CXR representing the shadow of three anatomical structures; the LSCA, the distal aortic arch and the proximal descending aorta. An alternate approach is to position the IABP tip at 2 cm above the carina, which will place the tip 1.5 to 3.5 cm distal to the origin of the LSCA.[31] The advantage of this approach is that the carina is a more clearly defined and visualized anatomic structure.

Transvenous Pacemakers

Transvenous pacemakers are introduced via the internal jugular or subclavian veins into the right ventricle in patients with heart block. Besides detecting a paced rhythm on an electrocardiogram, a CXR should also be performed promptly after the procedure to confirm correct placement of the leads and exclude complications such as pneumothorax. On a PA view CXR, the tip of the catheter should be at the apex of the right ventricle. Abnormal positions of the catheter tip, including coiling in the right atrium, and passage into the pulmonary artery, inferior vena cava as well as coronary sinus, have been described.[32] There should be no sharp angulations along its length—this would suggest fracture of the pacing wire or a strong predisposition for this complication to occur.

Non-displaced or partial fractures of the leads may not be detected on CXR at all—failure of pacing would then need further investigation with a CT. On the lateral view CXR, the tip should be 3 to 4 mm beneath the epicardial fat stripe. If the tip projects beyond this point, it may have perforated the myocardium. Perforation can be very subtle, since the right ventricle myocardium is only 4 to 5 mm in thickness and the lead can come to lie in the pericardial space within the shadow of the mediastinum (Fig. 145.9).[32] Failure of pacing, the appearance

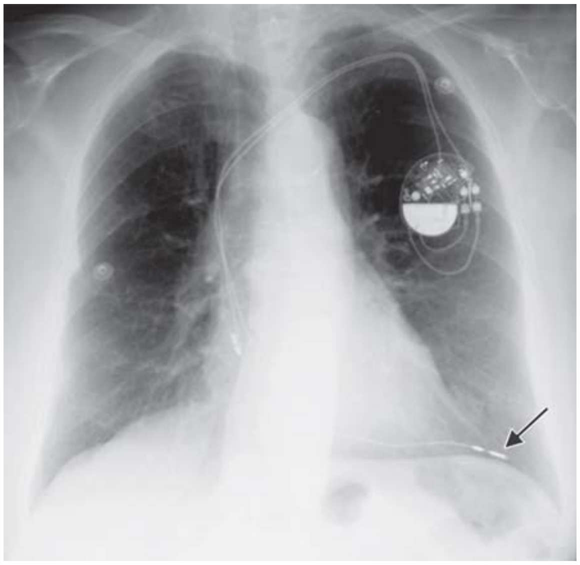

Fig. 145.9: Perforation of myocardial wall by pacemaker wire (see arrow)

of a new right bundle branch block, intractable hiccups from stimulation of the phrenic nerve or diaphragm, or signs of cardiac tamponade from hemopericardium are clinical clues that may herald myocardial perforation. Again, a CT may clinch the diagnosis if the CXR is inconclusive.[33]

Abnormal Air Collections in the Chest

Collection of air outside the tracheobronchial tree is not an uncommon occurrence in the ICU patient and heralds the presence of trauma from instrumentation or barotrauma from mechanical ventilation. The CXR is an invaluable tool for the prompt recognition of such complications, which can manifest as pneumothorax, pneumomediastinum, pneumopericardium or subcutaneous emphysema.

Pneumothorax

Pneumothorax is noted as a complication of internal jugular vein cannulation in 0.1 to 0.2% of cases and with subclavian vein cannulation in 1.5 to 3.1% cases.[34] In patients with ARDS, the reported incidence of pneumothorax from barotrauma varies widely from 6.5 to 60%.[35,36] Finally, rupture of lung bullae or cavities into the pleural space, either spontaneously or in the setting of positive pressure ventilation, can also give rise to pneumothoraces, as can traumatic attempts at intubation (Figs 145.6 and 145.7). The area on the CXR where a pneumothorax is likely to be visualized depends on the position of the patient when the CXR image was acquired. In the erect patient, air rises to the apicolateral surface of the lung and appears as a thin, white pleural line with no lung markings beyond it, unless the patient has a localized pneumothorax. In the recumbent position, air accumulates anterior to the lung and medially, surrounding the mediastinal structures. These anteromedial pneumothoraces can further be divided into those which are superior or inferior to the pulmonary hilum. On the right, sharp visualization of the superior vena cava and azygous vein suggest a superior anteromedial pneumothorax, whereas on the left this is suggested by sharp visualization of the left subclavian artery. Inferior or infrahilar anteromedial pneumothorax results in sharp delineation of the heart border and a lucent deep cardiophrenic sulcus.

Although the anteromedial location of the pneumothorax is more common in the supine patient (38% cases), an alternative location is the subpulmonic region, where air is trapped between the lung and the diaphragm (20% cases).[37] Air may extend into the costophrenic sulcus causing radiolucency, this is called the “deep sulcus sign” (Fig. 145.10). Alternatively, air may highlight both the relatively more superior anterior diaphragmatic surface and the inferior posterior diaphragmatic surface, resulting in what is known as the “double diaphragm sign”.[38]

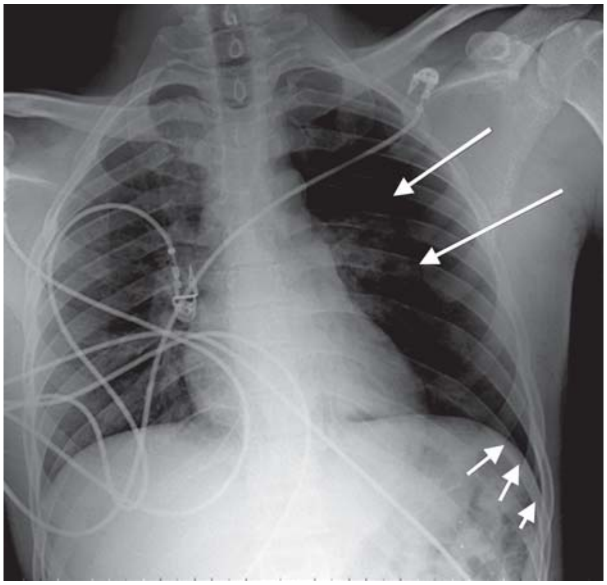

Fig. 145.10: Left pneumothorax (large arrows pointing to collapsed lung margin). Note the left costophrenic angle (small arrows) which is deepened due to the accumulation of air – the “deep sulcus sign”

Entry of air into the pleural space with no mechanism for exit (the so-called ball-valve effect) can result in a tension pneumothorax. This is a clinical diagnosis and should be managed with immediate decompression of the pleural space using a wide-bore IV catheter followed by a chest tube; no time should be lost waiting for a CXR to make this diagnosis. On CXR, the usual signs of total lung collapse and contralateral mediastinal shift may be absent in the setting of severe parenchymal lung disease and resulting low lung compliance. Flattening or even inversion of the ipsilateral hemidiaphragm, and flattening or shift of the superior or inferior vena cava, may be the only signs heralding a tension pneumothorax.

The presence of skin folds, wires, tubes and superimposed bony shadows can make the detection of a pneumothorax on CXR a treacherous business. Skin folds usually cause a broad, opaque band, with a zone of increased density leading up to the actual fold line and lung markings visible beyond the edge (Fig. 145.11). Furthermore, skin folds may extend across the midline or beyond the confines of the chest wall. In contrast, a pneumothorax is ideally visible as a thin pleural line with no lung markings beyond it.

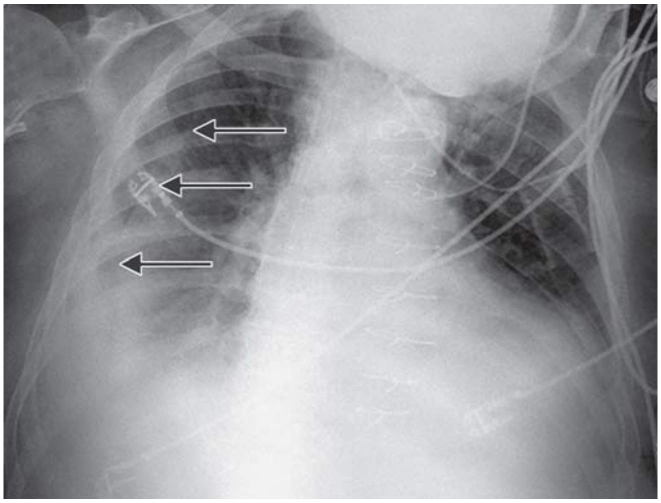

Fig. 145.11: CXR on an obese patient showing a broad, opaque band, with a zone of increased density leading up to a line (see arrows), and normal lung markings visible beyond the edge. This is typical of a skin fold, but can easily be mistaken as a pneumothorax. Note also a dense opacity at the right base tracking up the right lateral chest wall, suggestive of a pleural effusion. Sternotomy wires, EKG leads and ventilator tubing complete the picture

Pneumomediastinum

Pneumomediastinum usually occurs from barotrauma in the setting of ARDS. Inhalation of cocaine or marijuana may also induce pnemothorax and pneumomedisatinum (Fig. 145.12). Air from ruptured alveoli dissects via the pulmonary interstitium into the mediastinum. Less commonly, tear of the posterior membranous tracheal wall during traumatic intubation, rupture of the esophagus or blunt thoracic trauma can also introduce air into the mediastinal space (Figs 145.6 and 145.7). Air then tracks into the cervical and retropharyngeal tissues, the retroperitoneal tissues as well as the chest and abdominal wall. On CXR, lucencies mark the medial borders of the superior vena cava, azygous vein, aortic knob, pulmonary arteries or the descending thoracic aorta. Air can also outline the central portion of the diaphragm under the cardiac silhouette, resulting in the "continuous diaphragm sign".

Pneumopericardium

Pneumopericardium can be seen in postoperative cardiothoracic surgical patients as well as with penetrating chest trauma. Just like a tension pneumothorax, a pneumopericardium with tamponade physiology warrants immediate decompression; management should not be delayed awaiting a CXR. Unlike pneumomediastinum, the air in pneumopericardium does not rise above the level of the aortic knob—the air is contained by the superior pericardial recess, which reflects off the root of the aorta and pulmonary artery (Fig. 145.13). Also unlike pneumomediastinum, the air in pnuemopericardium can track around the pulmonary artery. In pneumopericardium, a band of lucency is

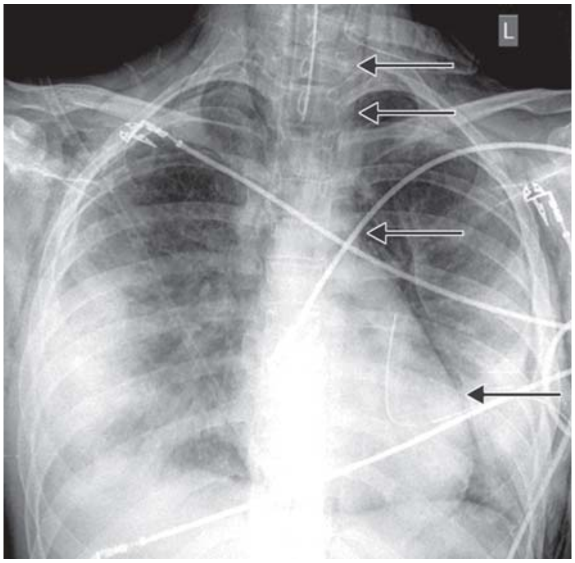

Fig. 145.12: Pneumomediastinum and left pneumothorax after marijuana use. There is a margin of air adjacent the left heart border extending above the aortic arch into the subcutaneous tissues of the neck (see arrows). An endotracheal tube is seen, as also multiple wires from EKG leads

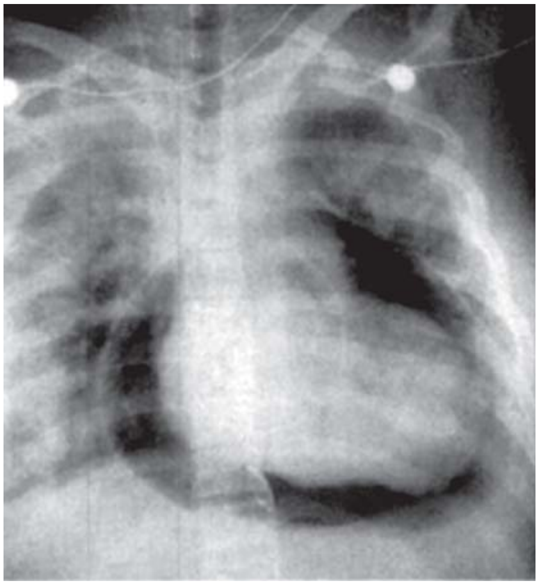

Fig. 145.13: Pneumopericardium. Note the air around the cardiac shadow, which does not extend above the aortic arch into the trachea or soft tissues of the neck

usually seen around the lateral and inferior aspects of the heart; a "continuous diaphragm sign" may be seen as well.

Subcutaneous Emphysema

Subcutaneous emphysema results from the dissection of air into the facial planes; as such the etiology is often similar to pneumothorax or pneumomediastinum. Iatrogenic subcutaneous emphysema can also occur as a complication of chest tube placement. It usually resolves spontaneously. Subcutaneous emphysema tracking through the pectoralis major muscles may sometimes obscure the underlying lung on CXR and make the evaluation of pleural and parenchymal disease difficult—a CT chest may be warranted in these situations.

Right Heart Catheterization

Vishal K Patel, Anthony Saleh

INTRODUCTION

In 1929 Dr Warner Forssmann introduced a catheter into his own heart and demonstrated that right heart catheterization is feasible in humans, although the catheter was advanced only into the right atrium. Later, Drs Cournand and Richards enhanced this catheter, which could be advanced into the pulmonary arteries. Drs Forssmann, Cournand and Richards were honored with the Nobel Prize in medicine for this invention in 1956.[1]

In 1969, after various improvements in the catheters, Drs Scheinman, Abbott and Rapaport developed a flow-directed right heart catheter to measure right heart pressures.[2] A year after that in 1970, Drs HJC Swan and William Ganz improvised the previous flow directed catheter by adding a balloon flotation feature and hence they are currently known as "Swan-Ganz catheters".[3] Further modifications in these catheters enabled them to measure cardiac output by thermodilution technique, to pace the right atrium and right ventricle, and to measure right-sided pressures including pulmonary capillary occlusion pressure.[4]

After its introduction into clinical practice, the catheter was used extensively in the management of critically ill patients. Most of the recent literature has suggested that while the catheter certainly offers significant theoretical advantages in the management of critically ill patients, there is no mortality benefit from this relatively invasive procedure. For this reason, Pulmonary Artery (PA) catheterization is now used in a very limited subset of patients (Table 146.1).

Setup

The PA catheter is a multilumen catheter of 110 cm length (Fig. 146.1). It is constructed from polyvinylchloride and is pliable. The most commonly used external diameter is 5 or 7 Fr. (1 Fr = 0.0335 mm). The distal port or PA port is located at the tip with a 1.5 cc balloon just proximal to it. When inflated, it guides the catheter from the right heart chambers into the pulmonary artery and it also protrudes beyond the catheter tip minimizing the chances of endocardial damage or arrhythmia. Typically the balloon is inflated with air, however, if a right-to-left intracardiac shunt or a pulmonary arteriovenous fistula is suspected then the balloon should be inflated with filtered carbon dioxide to avoid rupture.[6] If carbon

TABLE 146.1: Indications and contraindications of PAC[5]

Indications	*Contraindications*
Diagnostic Diagnosis of shock states	1. Tricuspid or pulmonary valve mechanical prosthesis 2. Right heart mass (thrombus and/or tumor)
Differentiation of high versus low pressure pulmonary edema	3. Tricuspid or pulmonary valve endocarditis
Diagnosis of primary pulmonary hypertension (PPH)	4. Coagulopathy
Diagnosis of valvular disease, intracardiac shunts, cardiac tamponade, and pulmonary embolus	5. Uncooperative patient
Monitoring and management of complicated acute myocardial infarction (AMI)	
Assessing hemodynamic response to therapies	
Management of multiorgan system failure and/or severe burns	
Management of hemodynamic instability after cardiac surgery	
Assessment of response to treatment in patients with primary pulmonary hypertension (PPH)	
Therapeutic Aspiration of air emboli	

dioxide is used, periodic deflation and inflation is required as carbon dioxide diffuses through the latex balloon at a rate of 0.5 ml per minute. Liquids should never be used for balloon inflation.

Approximately 4 cm proximal to the balloon is the thermistor to measure temperature changes for calculation of Cardiac Output (CO). In the most commonly used quadruple-lumen catheter, two additional ports are present at 19 cm and 30 cm from the tip. Also available, a five-lumen catheter has an additional port at 40 cm from the tip, which can be used for fluid or medication infusion. Some catheters are coated with heparin and some have connections for temporary ventricular pacing.

Pressure Transducer

The conversion of the changes in the intravascular pressures into an electrical signal is done by a catheter-tubing-transducer system. Transmission of pressures from the catheter to the display system is achieved via connecting it to a semi rigid, noncompliant tubing filled with isotonic saline. This is then connected to a fluid-filled pressure transducer. This system accurately transmits intracardiac pressures to the transducer, causing small amounts of movement in the transducer membrane. This movement generates a proportional electric current that is amplified and transmitted to the monitor.

Insertion

The PA Catheter (PAC) is usually inserted percutaneously into the internal jugular, subclavian or femoral veins. The right internal jugular has the shortest and straight path to the heart and the left subclavian does not require the PAC to pass and course at an acute angle to enter the SVC (preferred over left internal jugular and right subclavian). The femoral vein approach may make it difficult to pass a PAC into the heart given the distance from the heart and often requires fluoroscopy; especially if the right sided heart chambers are enlarged.

Venous access is done in the Trendelenburg position, while the insertion of the PAC can be done in a flat or slightly upright position under sterile technique. Before insertion, it is important to check the PAC for kinks and balloon integrity. Connect all the lumens to stopcocks and flush them all with isotonic saline to eliminate air bubbles. Flick the PAC tip to check the response on the monitor after connecting it to the transducer. Finally, the PAC is passed through a sterile sleeve before insertion to ensure sterility.

The preformed curve of the PAC is adjusted before insertion to facilitate entry into the PA. Once the catheter displays the right atrial pressure waveforms (at approximately 10–20 cm mark), the balloon is slowly inflated with air. The catheter is passed down stream to obtain Right Ventricular (RV), PA and PA Occlusion Pressures (PAOPs). Inflation of the balloon facilitates the advancement of the catheter and prevents perforation.[7] The catheter is always withdrawn with the balloon deflated to avoid rupture or injury to the vessel. Usually, the right atrium is entered at 15–20 cm, the right ventricle is entered at 25–30 cm and the PAOP can be identified at

40–50 cm. It is essential to monitor the electrocardiogram during the insertion of the PA catheter in the RV because of the possibility of arrhythmias.

Special Considerations

Patients should have normal coagulation parameters before a central venous access is attempted; however, patients on anticoagulation are frequently seen in the ICU setting. Intravenous heparin should be discontinued 3–4 hours prior to the procedure. If the patient is on warfarin, then the INR should be normalized using fresh frozen plasma prior to the procedure.

In certain conditions such as, severe right atrial or right ventricular dilatation, severe pulmonary hypertension, severe tricuspid regurgitation and low cardiac output states, it may be difficult to position a flow-directed catheter and this may warrant the use of fluoroscopic guidance. Infusion of 5–10 ml of cold saline through the distal lumen may stiffen the catheter and may help in positioning the catheter.

Interpretation

Once the PA catheter has been inserted it becomes imperative to appropriately interpret the available data. PA catheterization allows measurement of right atrial, right ventricular, PA and PA occlusion pressure along with cardiac output, mixed venous oxygen saturation and oxygen saturation in the right-sided chambers to detect intracardiac shunting.

End exhalation provides an optimal reference point for PAOP because pleural pressure returns to baseline at the end of exhalation. Pleural pressures can be higher with active expiratory muscle contraction or with the use of Positive End Expiratory Pressure (PEEP).[8]

Normal resting right atrial pressure is 2–8 mm Hg. Two major positive right atrial waves are usually recorded; the A wave and V wave. The A wave is produced by atrial contraction and follows the electrocardiographic P wave.[9] The A wave peak generally follows the electrocardiographic P wave peak by 80 msec.[10] The V wave is produced by venous filling of the right atrium while the tricuspid valve is closed. The peak of the V wave occurs at the end of ventricular systole when the atrium is maximally filled. This follows the electrocardiographic T wave. A third wave known as the C wave, is a minor positive wave due to sudden motion of the atrivoventricular valve ring towards the right atrium and can be seen in cases of P-R prolongation. The X descent follows the A wave and is due to atrial relaxation and the Y descent follows the V wave and is due to rapid emptying of the right atrium (Fig. 146.2).

Normal resting right ventricular pressure is 20–30/0–8 mm Hg. The right ventricular systolic pressure equals the PA systolic pressure except in cases of pulmonic stenosis or RV outflow tract obstruction. The right ventricular diastolic pressure equals the mean RA pressure during diastole when the valve is open. The right ventricular waveform is identified by a sudden upstroke (and down stroke) in the tracing.

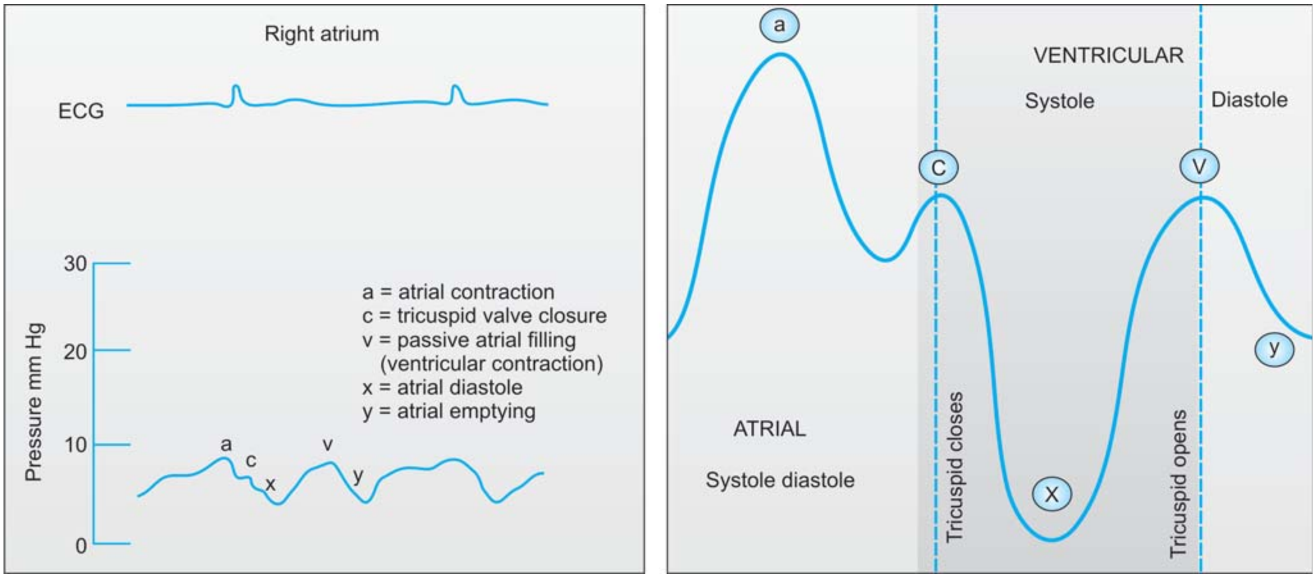

Fig. 146.2: Right atrial waveforms[11,41]

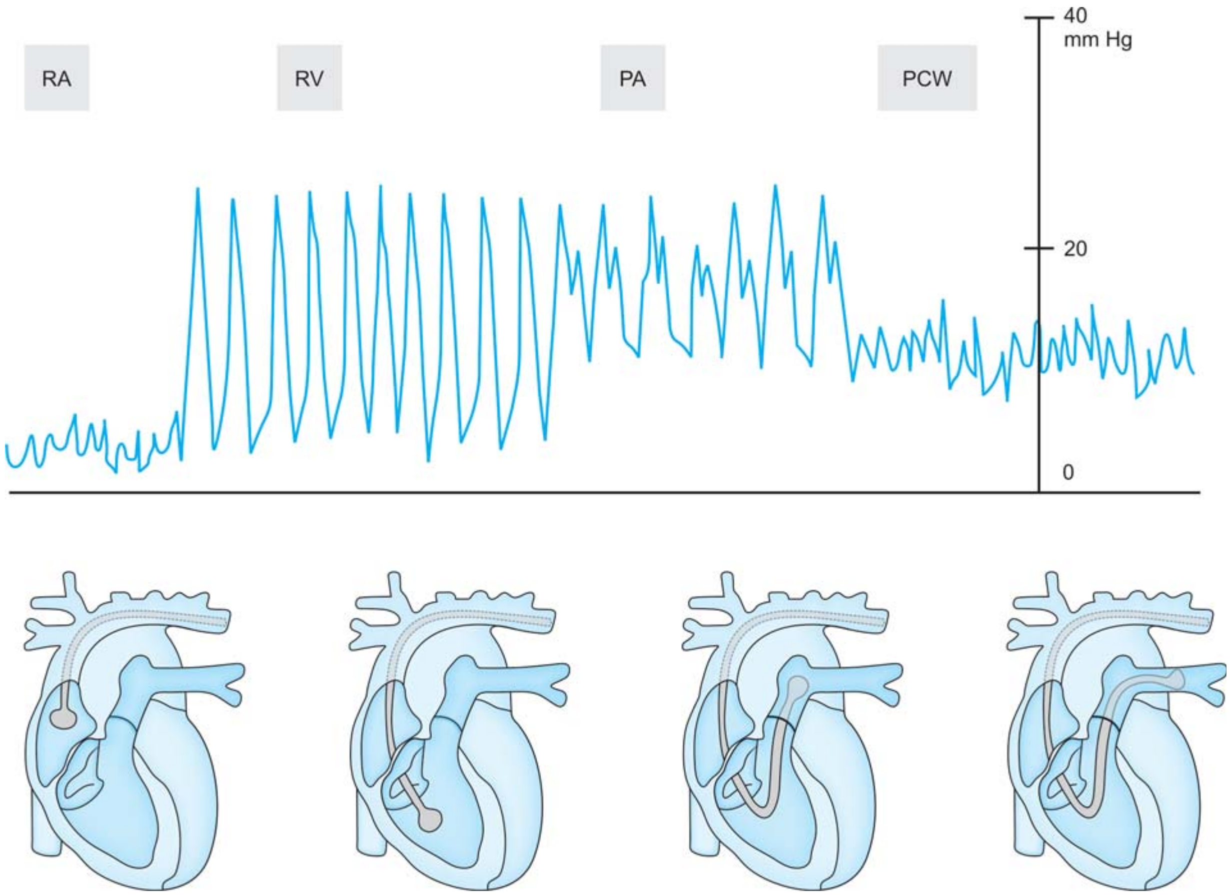

Fig. 146.3: Typical waveform progression as the PAC floats through the cardiac chambers[12]

Normal resting PA pressure is 20–30/5–13 mm Hg. The PA waveform is characterized by a systolic peak and diastolic trough with a dicrotic notch due to closure of the pulmonic valve. PA diastolic pressure is usually 1–3 mm higher than Pulmonary Artery Occlusion Pressure (PAOP) (Fig. 146.3). Thus, the PA diastolic pressure can be used as an index of left ventricular filling pressure in patients in whom an occlusion pressure is unobtainable.

Normal PAOP is 2–12 mm Hg. The PAOP waveform is similar to right atrial waveform except the V waves on PAOP are larger than the A wave. Once the PAOP is obtained, the balloon should be deflated to produce PA waveforms again. Wedge position can be confirmed by withdrawing a blood specimen from the distal lumen and measuring the oxygen saturation from the sample. It confirms the wedge position, if the measured oxygen saturation is higher than 95%. Mean PAOP correlates with left ventricular end diastolic pressure (LVEDP), provided the patient has a normal mitral valve and normal left ventricular function. PAOP estimates pulmonary venous pressure and therefore left atrial pressure, on if the catheter tip is in the zone 3 of the lungs. In zone 3 pulmonary arterial and venous pressures are greater than alveolar pressures, providing an uninterrupted column of blood between the catheter tip and the pulmonary veins.[13] A catheter wedged outside zone 3 shows marked respiratory variations and irregular vascular waveforms which cause a misinterpretation of reading higher pressures (Fig. 146.4).

Once the catheter has been appropriately inserted and adequate position is verified, the critical job of interpreting the data accurately and making the necessary interventions is left up to the clinician. There are a variety of conditions, which can be either definitely diagnosed (VSD, pulmonary hypertension) or highly suggested (cardiogenic pulmonary edema, cardiac temponade) via PA catheterization. Additionally, certain conditions such as septic shock, hypovolemic shock and pulmonary embolism can be confirmed with PA catheterization (Table 146.2).

Complications

The PA catheterization is associated with a variety of complications. These can be divided into those related to central venous catheterization and those specific to the PA catheter.

The complications associated with central venous access can be seen during right heart catheterization. The reported complications include local hematomas; injury to thoracic duct, carotid artery; pneumothorax and pseudoaneurysm formation. Pulmonary infarction is a potentially preventable complication of PA catheterization caused by distal migration of the PA catheter tip into the smaller branches of the PA causing persistent wedging.[14] It is also seen if the balloon is left inflated in the wedge position for an extended period of the time.[15] A potentially fatal and feared complication of PA catheterization is rupture of the pulmonary artery. It has been reported in 0.1 to 0.2% of patients with a mortality of 45 to 65%.[16,17] It can occur during insertion or a few days after insertion.[18] It presents typically with massive hemoptysis and emergency management includes immediate angiogram with embolization, selective intubation of the unaffected lung and/or lobectomy.

The PA catheter, being a foreign body in a vascular system, can damage the endothelium and cause thrombosis. These thrombi can encase the tip of the catheter or form anywhere in the venous system acting as pulmonary emboli. A changing relationship between PADP and PAOP over a period of time should

TABLE 146.2: A summary of PA catheter findings in selected clinical situations[43]

increase suspicion for thrombosis at the tip. Knotting of the catheter results when the catheter forms a loop in the cardiac chamber and the catheter is repeatedly withdrawn and advanced.[19] Knotting is avoided by not advancing the catheter beyond the approximately anticipated distance. Knotted catheters can be removed transvenously or surgically. Knotting of the PA catheter around intracardiac structures, other intravascular catheters, and intracardiac sutures has been reported.[20-22] The main problem associated with balloon rupture is air emboli gaining intravascular entry and/or balloon fragments embolizing into the distal pulmonary circulation. If the rupture occurs during catheter insertion, the loss of the balloon's protective function can cause endocardial damage and/or arrhythmia. Atrial and ventricular arrhythmias are common during insertion of a PA catheter. Most arrhythmias are self-limited and do not necessitate treatment; however, up to 3% of sustained arrhythmia may warrant treatment.[23,24] Transient right bundle branch block can be seen during catheter insertion. Patients with pre-existing left bundle branch block can be at risk of complete heart block due to transient right heart block during catheter insertion.

Damage to the right atrium, right ventricle, pulmonic valve, tricuspid valve and supporting chordate can occur during insertion or withdrawal of the catheter. It is primarily seen while withdrawing a catheter with the balloon inflated.[3] Catheter related infections, which can be seen with the central venous access catheter, are also seen with PA catheters.

Clinical Controversy

A variety of studies from 1980 to 2000 showed a greater mortality rate in patients who underwent placement of a PAC than in those who did not. A great clinical controversy ensued from these studies as critics claimed the acutely ill patients in the ICU are more likely to undergo PAC. Since, then a number of randomized clinical trials have been published:

- In 2003 a study by Sandham et al of nearly 2000 surgical patients (ASA class 3 or 4) aged 60 years or older, randomized PAC to guide therapy versus central venous catheter and therapy on physician's discretion. Results showed no difference in mortality, length of stay or organ dysfunction.[25]
- A study by Richard et al looked at 700 patients with early shock, ARDS, or both. There was no significant difference in mortality or morbidity in patients treated with or without PAC.[26]
- Rhodes et al showed no difference in 28-day mortality, ICU or hospital length of stay in patients with or without a PAC. However, a formal management protocol was not used.[27]
- An important study, recently published in 2005 was the PACMAN trial. This trial enrolled more than 1,000 patients. There was no difference in mortality (primary outcome) in patients treated with or without a PAC.[28]
- Another trial published in 2005, the ESCAPE trial demonstrated no difference in overall mortality or hospitalization in more than 400 patients who were admitted with severe heart failure. Patients were randomized to clinical assessment guided therapy versus PAC.[29]
- A large meta-analysis done by Shah et al including 13 randomized clinical trials and more than 5,000 patients did not show any significant benefit from the use of a PAC.[30]
- In 2006, the ARDSNET group evaluated the role of the PAC in acute lung injury patients. Patients were randomized to hemodynamic management with either a PAC or a Central Venous Catheter (CVC). It did not show any difference in mortality (primary outcome), ICU length of stay, or lung function.[31]
- Published in 2006, a study of PAC use in cardiac surgery patients by Djaiani et al showed that the use of PAC derived data lead to more interventions but no overall clinical benefit.[32]
- A Cochrane Review of 12 studies was only able to support the need for efficacy studies, to determine optimal the patient groups who could benefit from management with a PAC.[33]

CONCLUSION

In summary, the literature does not show a beneficial effect on patient outcome with PAC use; however, a criticism of the current available research is that the patient groups studied are the ones which gain little or no benefit from PAC use. Chittock et al published an observational cohort study showing that PAC use was associated with increased mortality in less acutely ill patients but decreased mortality in more acutely ill patients.[34]

The use of a monitoring tool, such as the PAC itself, is unlikely to show a significant treatment effect. Some criticize the current literature because a number of studies did not use a predefined treatment protocol. The lack of defined specific treatment based on measured PAC-derived variables could contribute more to patient outcome than merely the presence or absence of a PAC. The other factors that impact mortality outcomes include operator competence, nursing dependent data information from PAC and physician-dependent interpretation of data and subsequent management. A time-trend analysis on national estimates of PAC use in the United States from 1993 to 2004, using data from the Nationwide Inpatient Sample, found a 65% decrease in PAC use during that period; the most prominent decline, by 81%, was in use of PACs for myocardial infarction.[35]

The newer noninvasive modalities to measure cardiac output using ultrasound or arterial pressure waveforms may provide a safer alternative to the PAC; however, more studies are needed to support their use.[36]

In conclusion, PACs remain an important tool, but they should be used only selected patients and only by well-trained physicians.[37-39] A concise review by Chatterjee offers some reasonable indications for ongoing PAC use; however, these unfortunately lack empiric evidence at present.[40]

Nutritional Management and General Care in the Intensive Care Unit

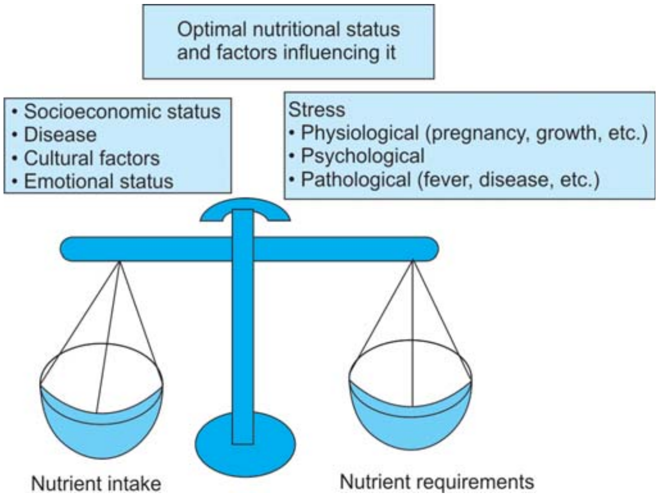
Navneet Singh

Malnutrition arises from an imbalance between the nutrient intake and the nutrient requirements (Fig. 147.1). Diseases especially the critical illnesses, are unique that they not only affect nutritional intake and requirements, but also increase nutrient losses (urinary, gastrointestinal or from other sites). Infact, multiple mechanisms are believed to be operating simultaneously in majority of the malnourished critically ill patients (Fig. 147.2).

MALNUTRITION IN CRITICAL ILLNESS

Prevalence and Epidemiology

The prevalence of malnutrition among hospitalized patients, including those in Intensive Care Unit (ICU), has increased steadily over the years because of several reasons, such as an increasing age of the general population, development of newer and often aggressive medical and surgical treatment modalities for different chronic debilitating diseases, and finally because of the progress achieved in intensive care management.[1,2] The prevalence of malnutrition among hospitalized patients is estimated to be as high as 30 to 50%.[3] Amongst patients admitted to the ICU, malnutrition is equally common, if not more.[4-6]



Optimal nutritional status
and factors influencing it
• Socioeconomic status
• Disease
• Cultural factors
• Emotional status
Stress
• Physiological (pregnancy, growth, etc.)
• Psychological
• Pathological (fever, disease, etc.)
Nutrient intake
Nutrient requirements

Critical illness
Reduced intake
Nutrient losses
Increased energy requirements
Deficiency
Reduced mass
Inefficient fuel utilization
Change in body composition
Change in physiologic and metabolic responses
Loss of reserve tissue and functional capacity
Malnutrition and homeostatic imbalances

Fig. 147.2: Mechanism of influence of critical illness on nutritional homeostasis

Malnutrition can be either present at admission or develop subsequently as a result of metabolic response to injury. The accelerated catabolic state occurring in critically ill patients can lead to rapid onset of malnutrition. Uncorrected malnutrition is succeeded by metabolic abnormalities, physiologic changes, reduced organ-cum-tissue function and finally, loss of body mass.[7] Malnutrition can affect the pulmonary system directly by causing a reduction in diaphragmatic muscle mass, respiratory muscle strength, maximum voluntary ventilation and functional residual capacity. It can also lead to a rapid shallow pattern of breathing pattern, increase in the quantity of interstitial fluid and predisposition to atelectasis.[8]

Any or all of these can be present in a patient on mechanical ventilatory support and make the process of weaning difficult. Nutritional supplementation provides an opportunity to slow down or even halt the catabolic process and thus prevent malnutrition, which in turn can favorably alter the hospital course of such patients. Optimal nutritional support is thus an essential component of patient care in acute or chronic critical illnesses in order to prevent and treat nutritional deficiencies. Heightened awareness of its importance has led it to become a routine part of management of patients in majority of ICUs.

Differentiation of Catabolism in Critical Illness from Starvation

It is important to differentiate catabolic state of critical illness from starvation (Table 147.1). One of the fundamental differences between the two is the Basal Metabolic Rate (BMR) which is elevated in a critical illness in contrast to starvation where it is depressed.[9] Ketogenesis is a prominent feature of starvation but not of critical illness.[7]

Effect of Malnutrition on Clinical Outcomes in Critically Ill Patients

In some studies, the incidence of complications, hospital length of stay and in-hospital mortality rates have been shown to be significantly higher in malnourished, critically ill patients as compared to those who are well-nourished.[4,6] Furthermore, presence of malnutrition is associated with worse outcomes even with a lesser severity of critical illness.[4] In patients admitted to the respiratory ICU at this institute, the mean daily calorie delivery of less than 50% of recommended values was shown to be independently associated with hospital mortality (Fig. 147.3).[10]

TABLE 147.1: Differentiation of catabolism in critical illness from starvation

Feature	*Catabolism in critical illness*	*Starvation*
BMR/REE	↑	↓
Respiratory quotient	(0.8-0.9)	(0.6-0.7)
Cytokine levels	↑	↓
Primary fuels	Mixed	Fat
Proteolysis	+++	+
Ureagenesis	+++	+
Urinary nitrogen losses	+++	+
Gluconeogenesis	+++	+
Ketone production	+	+++

BMR = Basal Metabolic Rate
REE = Resting Energy Expenditure

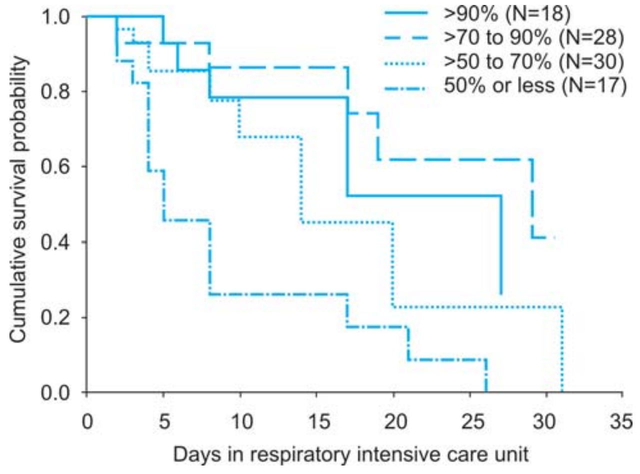

Fig. 147.3: Kaplan-Meier analysis for probability of survival stratified according to mean calorie delivery (as percentage of recommended values). Mean calorie delivery of less than 50% of recommendations reduced the probability of survival significantly. [Reproduced with permission, from Singh N, Gupta D, Aggarwal AN, et al. Respir Care. 2009; 54(12):1688-96]

No differences were seen between the well-nourished and the malnourished patients with regard to either length of stay or in-hospital mortality in other studies.[5] These discrepancies were explained, in part, by the complexity of the relationship between the underlying conditions which mandated ICU admission and mortality.[11] Variations in the reported prevalence of malnutrition as a result of differences in type of screening tools used for its detection can also explain the difference. Among the other clinically relevant outcomes, nosocomial infections have been shown to be more frequent in malnourished ICU patients.[12]

ASSESSMENT OF NUTRITIONAL STATUS IN CRITICALLY ILL PATIENTS

Assessment of nutritional status includes evaluation of clinical, anthropometric, chemical and immunologic parameters. Patient history should include details of diseases that are associated with heightened risk of malnutrition especially of the chronic debilitating diseases, history of inadequate food intake over prolonged periods of time, drug abuse, alcoholism and chronic psychiatric disorders. Physical examination should include nutrition focused physical examination, anthropometry and body composition/circumference measurements.

All the tests used for assessment of nutritional status have their own limitations, hence there is no single test that is sensitive and specific enough on its own to detect malnutrition in critically ill patients.[13]

1. **Body weight:** Alteration of nutritional status and protein calorie malnutrition is usually accompanied by weight loss. Unintentional loss of body weight (more than 10% in six months or more than 5% in one month) is clinically significant and suggestive of malnutrition.[14] Critically ill patients are often edematous due to progressive retention of salt and water. Body weight may not reflect the actual body cell mass in such cases. Moreover the 'normal' reference value for a particular patient is difficult to define because of the marked heterogeneity of race, body built and age in the control population leading to a wide range of normal values. Measured body weight can be compared to Ideal Body Weight (IBW), can also be used in association with height to calculate Body Mass Index (BMI).
2. **Anthropometry:** Anthropometric measurements provide an objective evaluation of fat and lean body mass. They are safe, simple, inexpensive and can be readily performed at the bedside of the patients including the critically ill patients. Body fat reserve and skeletal muscle mass can be assessed by carrying out measurements of Skin Fold Thickness (SFT) and Mid Arm Muscle Circumference (MAMC) respectively.[15] Measurement of SFT is based on the assumption that almost half of the total body fat is distributed in the subcutaneous region but this can vary from 20 to 70% in normal subjects. Commonly, triceps SFT is measured but subscapular, iliac crest and upper thigh are other areas that can be used. The normal values of these anthropometric measurements vary with age and gender.[16] There is also a tendency for over and under-estimation of body fat in the malnourished and obese patients respectively. Fluid shifts that occur acutely in critically patients especially those who receive aggressive fluid resuscitation may alter the reliability of these measurements.[13,14]
3. **Hepatic secretory proteins:** Albumin, prealbumin, transferrin, retinol binding protein and other proteins secreted by liver are used as indicators of nutritional status since they reflect visceral protein stores.[17] Hepatic synthesis of these proteins is reduced in cases of acute infection/inflammation, they are referred to as negative acute phase reactant proteins [as compared to positive acute phase reactants like C-reactive Protein (CRP), fibrinogen and α-1 glycoprotein whose synthesis is increased under similar conditions]. However, these proteins have different half-lives and their serum levels are influenced by factors other than nutritional status such as abnormal hepatic function, hydration status, protein losing diseases and acute infection/inflammation.[13,18,19] Despite the limitations, one or more of these proteins continue to be used for predicting patient outcomes.[20,21] In the author's experience, higher baseline serum albumin levels are observed among critically ill patients who survive, compared to the non-survivors.[10]
4. **Others:** The other parameters that have been used for nutritional assessment include Total Lymphocyte Count (TLC) and Delayed Cutaneous Hypersensitivity (DCH).[22] Blood/serum levels of electrolytes like potassium, phosphorus, calcium and magnesium are useful markers of adequate supplementation, and these key electrolytes should be monitored with a frequency that depends upon the anticipated abnormalities, in their levels.
5. **Multiparameter nutritional indices:** These parameters are used to overcome the sensitivity and specificity problems associated with single nutritional assessment tests. Examples include Subjective Global Assessment, Prognostic Nutritional Index Prognostic Inflammatory and Nutritional index.[5] Even though these multiparameter indices are objectively designed, they rely on the values of different clinical and laboratory parameters, hence are limited by the same concerns as the individual parameters themselves.

GOALS AND PRINCIPLES OF NUTRITIONAL SUPPORT

General goals of providing nutritional support to the critically ill patients include:

1. Provision of nutritional support to the patient after taking into consideration his/her medical condition, nutritional status, existing metabolic requirements and the route available for administration of nutrients.
2. Prevention and treatment of both macro-and micronutrient deficiencies.
3. Avoidance of complications associated with nutritional support (enteral and/or parenteral).
4. Improvement in outcomes related to disease morbidity.

TIMING OF INITIATION OF NUTRITIONAL SUPPORT

The timing of initiation of nutritional support has been an area of intense debate. Nutritional support is indicated in any critically ill patient who suffers from malnutrition (of any etiology) and is unable to eat. Many patients, especially those who are previously well-nourished, can tolerate short periods of starvation (usually of less than one week) during a critical illness. Even in well-nourished patients, nutritional supplementation is necessary if they are unable to resume oral nutrition or if their oral intake is insufficient for more than three to four days.[1] When a greater severity of critical illness is present, this delay should be shortened to one to two days or less since the deprivation of nutrients and/or presence of a hypercatabolic state even for a short period of time is likely to be associated with increased morbidity and mortality. Enteral nutritional support can thus be started as early as 12 to 48 hours of admission to the ICU. In most critically ill patients oral-feeding may not be feasible and hence enteral nutritional support should be attempted after placement of a nasogastric (or in some cases nasojejunal) tube. It has been amply shown that aggressive initiation of early enteral nutrition (EN) to mechanically ventilated patients was associated with greater complications.[23]

In a retrospective analysis of a multi-institutional ICU database involving 4049 mechanically ventilated medical patients, it was observed that 63% of the patients who had received early enteral nutritional support (within 48 hours of initiation of mechanical ventilation [MV] (early feeding group) had better outcomes compared to the remaining 37% patients (late-feeding group).[24] The early feeding group had lower ICU and hospital mortality rates. The lower mortality rates in the early feeding group were most evident in the sickest group as defined by quartiles of severity of illness scores. The early feeding group, however, had a higher incidence of Ventilator-Associated Pneumonia (VAP). Therefore the authors had suggested that routine administration of early feeding may be warranted in medical patients receiving MV who are at high-risk of death.

In a systematic review of 15 prospective Randomized Controlled Trials (RCTs) involving a heterogeneous population of 753 adult ICU patients, effects of early EN were compared to delayed EN (initiation of nutritional support within and after 36 hours respectively).[25] Early enteral nutrition was associated with a significantly lower incidence of infections (relative risk reduction = 0.45 EN) and a reduced length of hospital stay (mean reduction = 2.2 days). Reduction in mortality in the early feeding group (8 vs 11.3%) did not reach statistical significance. No difference was however, found between the two groups in terms of non-infectious complications.

Consensus statements have also chosen to differ over the optimal time of initiation of nutritional support. A consensus statement of the American College of Chest Physicians recommended that enteral EN be initiated as soon as possible after resuscitation in ICU patients when significant preexisting malnutrition is present (BMI under 16).[13] The Working Group on Nutrition and Metabolism of the European Society of Intensive Care Medicine had recommended that enteral feeding should be initiated as early as possible in ICU patients.[1] There are others who recommend that nutritional support should be started in patients who are not expected to resume oral feeding for a "prolonged" period of time (7 to 10 days).[26]

The latest practice guidelines from Society of Critical Care Medicine and American Society of Parenteral and Enteral Nutrition for the provision and assessment of nutrition support therapy in the adult critically ill patient give a grade C recommendation about starting enteral feeding early (within the first 24 to 48 hours following admission).[27] The aim of starting enteral feeding as early as possible is not necessarily to provide nutritional support alone but also to have other beneficial effects on the gut, which can be attained with even small amounts of enteral feeding.

ROUTE OF ADMINISTRATION OF NUTRITIONAL SUPPORT

Nutritional support may be given by either the enteral or parenteral route or both. There is increasing evidence to suggest that, in the presence of a functional gut, nutrition should be administered by the enteral route, whenever possible. It is also becoming quite clear that the consequences of EN go beyond the supply of nutrients to the body.[28] Modulation of the host's immune response and the provision of energy and protein to maintain gut integrity could be some of the possible reasons for the same. Enteral nutrition favors maintenance of structure and functioning of intestinal villi (both by reducing the incidence of mucosal atrophy as well decreasing the abnormal increase in intestinal permeability) and thus promotes gut motility which eventually helps in initiating oral feeding.[29]

The proposed mechanisms for the beneficial effects of EN on the gut include stimulation of epithelial cell metabolism by direct contact with nutrients, increase in mucosal blood flow, and secretion of IgA and enterotrophic hormones like gastrin and enteroglucagon.

Enteral nutrition is also less expensive, leads to improved utilization of nutrients, and possibly helps to avoid some of the infectious complications associated with parenteral nutrition (PN), one of the mechanisms being reduction in translocation of bacteria from the gut.[30]

Comparison of Enteral with Parenteral Nutrition—Evidence from Published Literature

In a meta-analysis based on 'intention to treat' principle of 11 trials that had compared EN to PN in critically ill patients, a mortality benefit was seen in favor of use of PN.[31] However, subgroup analysis showed that the benefit from its use was only apparent in trials wherein initiation of EN had been delayed beyond 24 hours. When the use of PN was compared to the provision of early EN, there was no difference in mortality. Incidence of infectious complications was significantly more with the use of PN. The authors recommended PN among patients in whom EN could not be initiated within 24 hours of ICU admission or injury. However, its relevance to medical ICU patients remains unclear, since a majority of the trials included in this analysis involved surgical and trauma patients.

A systematic review of 13 RCTs which compared enteral and parenteral nutritional support in terms of outcome of critically ill adult patients, and included a heterogeneous population of 807 ICU patients showed that the use of EN in comparison to PN, was associated with significant reduction in the incidence of infectious complications as well as reduction in cost of nutritional support.[32] There was no difference in mortality, duration of MV or length of hospital stay. Moreover, use of PN was associated with an increase in the incidence of hyperglycemia in addition to the total administered calories. This analysis again showed that EN should remain the first choice for nutritional support in the critically ill.

Comparison of early EN with early parenteral nutrition among hospitalized patients was done in a meta-analysis, which involved 30 RCTs and PN, included 2430 critically ill medical, surgical and trauma patients. No significant difference was found between the groups receiving early EN and early PN in terms of hospital mortality.[33] The definition of early EN or PN used herein was the institution of supplemental nutrition within 96 hours of hospitalization, ICU admission or surgery. The results held true even when subgroup analysis was carried out separately for medical, surgical and trauma patients. Use of PN, however, was associated with an increased incidence of infective (including catheter related bloodstream infections) and non-infective complications as well as prolongation of length of stay in the hospital. Importantly among medical patients, in addition to the above, technical complications were also observed to be more frequent with use of PN. The only complication that was observed to be higher with use of EN was the incidence of diarrhea. Thus, even though no mortality benefit was shown in this analysis, EN was shown to have significantly less complications as compared to PN in the setting of early initiation of nutritional support.

In spite of the preferences for the enteral route, PN remains "a valuable yet challenging weapon in our therapeutic armory in the presence of gastrointestinal feed intolerance or failure. It should be used wisely and not indiscriminately, since most intensive care patients with a fully functional gastrointestinal tract can be fed safely with enteral nutrition".[34]

Addition of Parenteral to Enteral Nutrition

There is a school of thought among intensivists that adding PN to EN leads to improvement in calorie delivery and therefore may positively influence patient outcomes. However, published literature seems to suggest otherwise. In a prospective, double-blind RCT, 120 patients admitted in two ICUs were randomized into 2 groups: EN plus PN (treatment group) and EN plus placebo (placebo group).[35] Patients received nutritional support for a period ranging from four to seven days. Although the study met its primary end points (increase in serum levels of retinol-binding protein and prealbumin at day seven in the treatment group), there were no differences between the two groups for the clinically relevant end points (ICU morbidity, length of ICU stay, immediate and long-term mortality).

A systematic review of five RCTs compared combined EN and PN to EN alone and included a heterogeneous population of 248 ICU patients.[36] In these studies, PN was initiated at the same time as the EN. There were no differences between the two groups in terms of mortality, rates of infection, hospital length of stay and duration of MV. Combining PN to EN lead to significant increases in the total amount of calories delivered, as well as the total cost. This review again led to the conclusion that in critically ill patients who are not malnourished and have an intact gastrointestinal tract, starting PN at the same time as EN provides no benefit in clinical outcomes over EN alone.

Contraindications to Enteral Nutrition

It is not uncommon to encounter absolute and relative contraindications for administration of enteral nutritional support. Enteral nutrition is absolutely contraindicated in patients with a nonfunctional gut due to intestinal obstruction, anatomic disruption, generalized peritonitis or severe intestinal ischemia. Normally, splanchnic blood flow increases in response to nutrient load, taken orally/ administered enterally. This response is lacking in patients who have reduced gut perfusion due to severe or prolonged shock. Even if it occurs, it may not be sustained and this ultimately leads to hampered digestion and absorption. Infact, early feeding during hemodynamic compromise/shock can further contribute to mesenteric ischemia, infarction and even perforation. Therefore, it is prudent to withhold enteral nutritional support until hemodynamic stability has been achieved.[27]

Relative contraindications to enteral feeding include the occurrence of abdominal distension with administration of enteral feeds, presence of localized peritonitis, intra-abdominal abscess or severe pancreatitis, patients with a terminal disease, comatose patients at high risk of aspiration and patients with short bowel (less than 30 cm).[1]

QUANTITY AND VOLUME OF NUTRITION SUPPORT

Recommendations and practice guidelines have been revised from time-to-time in relation to the quantity of nutritional support to be administered to critically ill patients.[1,27,37] These recommendations can be broadly discussed under the following subheadings:

1. **Energy (Calorie) requirements:** For most patients, provision of calories in the range of 20 to 30 kcal/kg per day is appropriate. Factors that should be taken into consideration while deciding the optimal amount for a given patient include gender, age, presence/ absence of pre-existing malnutrition, type and severity of critical illness as well as the phase of critical illness (acute vs recovering). The target goals for energy (calorie) delivery should be determined at the time of initiation of nutritional support. It is desirable to achieve the goal of providing the entire energy requirements by the enteral route alone within the first 7 to 10 days of hospitalization. In case the same is not possible, initiation of supplemental PN should be considered.
2. **Protein requirements:** Protein delivery should be fixed between 1.2 to 1.5 gm/kg body weight per day (maximum 2.0 gm/kg body weight per day). Patients with extreme protein losses (e.g. extensive burns, digestive or urinary losses) can be given higher intake.
3. **Volume requirements:** In general, approximately 1 ml of water is needed per kcal while administering enteral feeds. However, fluid requirements and restrictions vary from patient-to-patient and therefore, the total volume to be administered may need to be individualized. The total amount of calories can be administered in a volume that is appropriate for the patient by changing the relative concentrations of the different constituents. The recommended proportion of carbohydrates, fats and proteins is 30 to 70%, 15 to 30% and 15 to 20% respectively of total calories.[1,13] For non-protein calories, carbohydrates and fat should be given in a ratio ranging from 1.5:1 to 2.5:1.
4. **Issues related to body weight:** Determination of body weight is an important issue for critically ill patients. It is neither easy to weigh patients in the ICU nor are such measurements free from errors since critically ill patients can have rapid and significant shifts in body water content. If direct weighing is not feasible, IBW can be estimated from height and anthropometric tables. The body weight used for calculating energy and protein requirements often needs to be modified according to the baseline nutritional status. Malnourished and obese patients generally require calorie delivery based upon determination of an "optimal" body weight.[38] The latter tends to fall in between their ideal and actual body weights and is higher or lower than the actual body weight for malnourished and obese patients respectively. Since, different formulae and methods have been proposed for such calculations and there is a lack of consensus, it is difficult to pinpoint the most accurate or appropriate method.
5. **Issues related to estimation of energy requirements:** More than 200 predictive equations (including the Harris-Benedict equation - the most well known of all of these) have been published for the assessment of energy requirements among critically ill patients.[27] By using the Harris-Benedict equation, the Resting Energy Expenditure (REE) can be calculated and subsequently the Total Energy Expenditure (TEE) estimated by multiplying REE with a Stress/Activity Factor (normally 1.2 to 1.4 in critically ill patients). Indirect calorimetry is another method used for this purpose and is probably more accurate than either the equations or simple formulae. However, using either the predictive equations or indirect calorimetry in routine ICU practice is not easy since these involve a lot of calculations and correction factors or are technically difficult. Also, it is unclear whether patient

outcomes will improve substantially if overworked staff and health care professionals in busy ICUs devote a significant percentage of their valuable time and effort in these calculations.

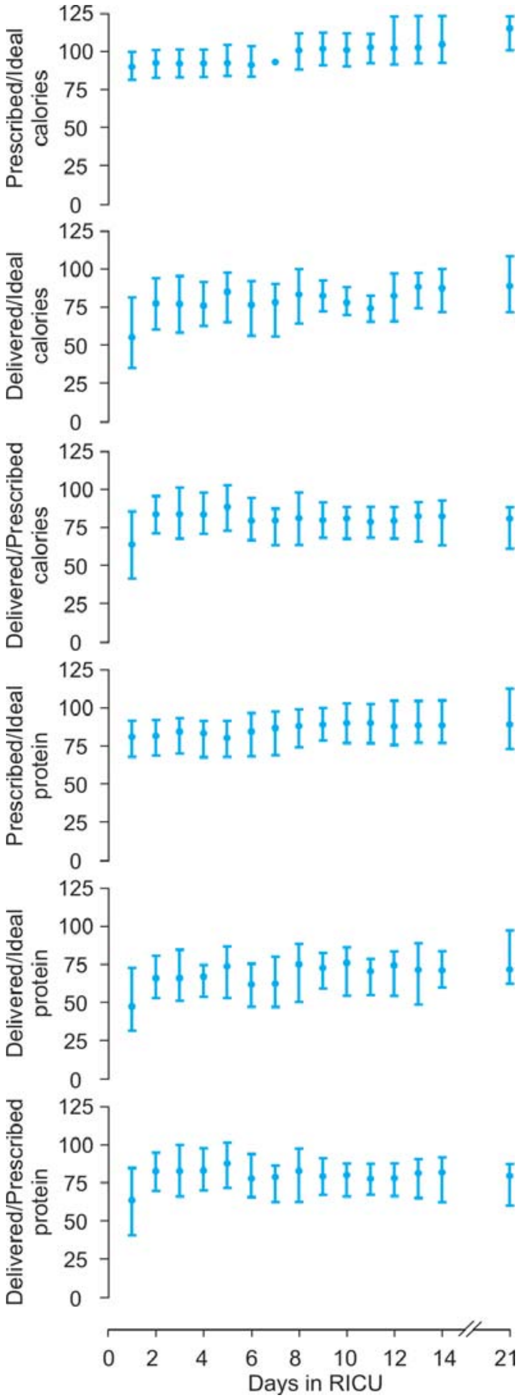

Fig. 147.4: Trend in prescriptions and delivery of calories and protein in relation to duration of stay in Respiratory Intensive Care Unit (RICU). Circles represent median values while lower and upper horizontal bars of plots represent the 25th and 75th percentiles respectively. Ideal calories and proteins correspond to recommend values of 30 kcal/kg/day for calories and 1.2 gm/kg/day for proteins. [Reproduced with permission, from Singh N, Gupta D, Aggarwal AN, et al. Respir Care. 2009; 54(12):1688-96]

DELIVERY OF ENTERAL NUTRITION AND ITS DETERMINANTS

The quantity of enteral feeds administered has been shown to be significantly lower than what is prescribed in as high as 40% of all hospitalized patients.[39] Other studies have shown that patients in ICUs also remain underfed.[40,41]

In a prospective study involving more than 400 ICU patients, successful administration (defined as 90% or more of the prescribed value) was achieved in only 52% of the total (n = 3526) feeding days.[42] Although the percentage of successful feeding days increased from 39% on day 1 to 51% on day 5, the overall average energy, protein and volume intake remained 54%, 66% and 75% respectively of the prescribed values. Feed intolerance was noted as an important impediment to successful nutrition delivery. Use of formulations with a higher energy and protein density has been suggested to enhance the total nutritional intake.

Prescription in Relation to Recommended Values

It is important to remember that, both the prescription and delivery are lesser for protein in comparison to those for calories. In a prospective study conducted at the author's institute, the median calorie and protein delivery for patients admitted to the Respiratory ICU (RICU) were 55.1 and 46.7% of the recommended values respectively on day 1.[10] It was not just delivery that was suboptimal. Even the median prescription of calories and proteins was 88.9 and 80.1% respectively of the recommended values on day one. The daily prescription and delivery of both calories and protein (as a percentage of recommended values) improved during the subsequent days of ICU stay (Fig. 147.4). A similar trend has been documented in previously conducted studies also.[43] Other studies that have compared actual prescription with recommended intake have also revealed protein delivery to be the area of largest overall deficit.[42,43]

Feeding interruptions because of diagnostic or therapeutic procedures remain an important reason for this reduced intake. High gastric residual volumes and mechanical feeding tube problems are other common reasons for decreasing or discontinuing feeds after initiation. Potential factors implicated for intolerance to feeds include the admission diagnosis, pre-existing illnesses, electrolyte and metabolic abnormalities, advanced age, and use of drugs (such as narcotics or catecholamines) and shock.[44] Elevated plasma cholecystokinin concentrations have also been shown to correlate with feed intolerance.[45]

Position of Feeding

Adoption of a semi-recumbent position while feeding patients is likely to have the best effect in terms of both tolerance to enteral feeds and patient outcomes. The frequency of clinically suspected and microbiologically confirmed pneumonia has been shown to be lower among patients fed in the semi-recumbent position as compared to those in the supine position.[46]

Nasogastric versus Nasojejunal Feeding

Nasogastric feeding is the most commonly employed method for administration of EN in critically ill patients. Abdominal X-ray should be obtained, if possible, after placement of a nasogastric tube to detect any malpositioning (looping inside the oral cavity or in the lower esophagus, or introduction into the trachea). Nasojejunal feeding has been shown to be associated with improved tolerance of EN, and therefore with a reduction in the requirement for PN.[47]

Although nasojejunal feeding leads to lesser gastrointestinal complications mainly because of a lesser incidence of high gastric residual volumes, it is also associated with increased frequency of tube related complications (occlusion, accidental withdrawal and dislodgement), and these can often negate its advantage(s) over nasogastric feeding. Moreover, in a prospective RCT, there were no differences between patients fed via the two routes in terms of feeding duration, length of ICU stay, and incidence of nosocomial pneumonia or mortality.[48]

Since nasojejunal tubes require endoscopic placement, use of this method, as is followed at the author's institute, should be reserved for patients who are intolerant to nasogastric feeding and in whom the intolerance is associated with inadequate nutrient delivery.[10]

Residual Volumes

Gastric residual volumes should ideally be measured prior to administration of each feed, or earlier if indicated. It is advisable to have minimal residual volumes (ideally less than 150 ml) in order to reduce the risk of aspiration of feed contents into the tracheobronchial tree. There is no 'minimum' level of residual volume that can identify patients at risk for aspiration.[49] It was observed that the frequency of aspiration and regurgitation did not change appreciably even if the residual volume increased from 0 ml to greater than 400 ml. Even when the residual volume was less than 150 ml, the frequency of aspiration was 23%.[49] There was also no correlation between the frequency of regurgitation/aspiration and the incidence of pneumonia.

In the presence of high gastric residues, a reduction in the frequency and volume of enteral feeds may be necessary along with more frequent monitoring of gastric residual volumes. Prokinetic agents (metoclopramide, cisapride or erythromycin) can be used to improve gastric emptying although the relative efficacy of one drug over the other or use of a combination versus a single drug is debatable.[50,51] In most cases, it is the gastric motility that is hampered (gastroparesis or gastric atony) and true ileus (dilated and non functional small intestine) is rare.

Role of Bowel Sounds

Bowel sounds should not be used as a criterion to determine initiation or interruption/discontinuation of enteral feeding.[27] The reasons are:

1. They do not correlate well with gut motility in critically ill patients.
2. Bowel sounds are produced due to movement of air through the small intestine and require the presence of both gastric air and gastric emptying. Critically ill patients who have nasogastric tubes *in situ* may not have either or both of these. Hence, there may be minimal or no movement of air from the stomach into the small intestine, and decreased/absent bowel sounds even in the presence of a normally functioning small intestine.
3. Most clinicians do not listen for bowel sounds for more than a few seconds, while one needs to listen for them for two to four minutes in each of the abdominal quadrants.

   Passage of flatus or stool is also not required for initiation of enteral feeding.[27,52]

Diarrhea and Enteral Nutrition

Patients on enteral nutritional support who develop diarrhea that persists for more than three days may need evaluation for *Clostridium difficile* infection after other common causes have been excluded, since these patients are usually receiving broad spectrum antibiotics. A decrease in the frequency and volume of enteral feeds may be required and in certain cases, transient use of PN may be needed to ensure adequate nutritional support. Administration of anti-diarrheal agents or probiotics like *Saccharomyces boulardii* can be considered, but are of unproven benefit.

GENERAL CARE IN ICU

Recommendations for general care of the critically ill patients often vary with the indication for ICU admission.[53-58] Several aspects of general care of the critically ill patient (Table 147.2) are covered in detail in the chapters on sepsis and sedation/analgesia as well as in the sections on respiratory monitoring and MV.

TABLE 147.2: Key components of general care of the critically ill patient

Hemodynamic and respiratory monitoring
Judicious use of sedatives, analgesics and neuromuscular paralyzing agents
Periodic assessments for weaning and tracheostomy
Prophylaxis against stress related mucosal disease
Prophylaxis against deep venous thrombosis
Glycemic control – avoid intensive insulin therapy
Prevention of pressure ulcers
Implementation of infection prevention strategies
Avoidance of unnecessary transfusions

Airway Protection

For most critically ill patients, supportive measures including the "ABC" (Airway, Breathing, Circulation) are required. Ensuring patency of the airway is a must for all patients admitted to the ICU. Endotracheal intubation is not always necessary when there is adequate presence of cough and gag reflexes, as well as of spontaneous ventilation. If there are any concerns regarding airway protection and/or of clinical deterioration, it is advisable to have the airway secured pre-emptively since endotracheal intubation reduces the risk of aspiration. Intubation is also indicated in cases of acute (or sometimes in acute-on-chronic) respiratory failure for providing assisted MV. (These issues are discussed in detail in a subsequent chapter on airway management).

Deep Venous Thrombosis Prophylaxis

Two important issues related to the management of critically ill patients need mention: prophylaxis against Deep Venous Thrombosis (DVT) and Stress Related Mucosal Disease (SMRD). In the absence of any specific contraindication, some form of DVT prophylaxis is advocated for most ICU patients. Both DVT and Pulmonary Embolism (PE) remain under-diagnosed among patients admitted to ICUs.[59,60] In a retrospective analysis of 12,338 patients from 12 ICUs, 2.0% patients were detected to have radiologically confirmed DVT or PE while 0.5% had possible DVT or PE.[59] A significant percentage of medically ill patients admitted to the hospital and the ICU, develop DVT-PE despite receiving prophylaxis.[59,61]

There is a general need for increased suspicion among clinicians for its diagnosis, renewed efforts at prophylaxis, and evaluation of superior prevention strategies. In a recent study from India, it was seen that only 12.5% of medically ill patients received DVT prophylaxis within the first two days of admission. Clinical signs and symptoms of DVT and PE were present in only about 25 and 10% of patients respectively.[62] Transthoracic echocardiography is being increasingly used as a triage tool for suspected PE.[63,64] A recently published review provides a concise overview on the management of PE in ICU patients.[65]

Mucosal Ulcer Prevention

Stress related mucosal disease or stress related mucosal ulceration is an important and frequently occurring gastrointestinal complication among ICU patients. This can be associated with increased length of stay in the ICU, can possibly adversely influence other clinically important outcomes. Suppression of gastric acid production is fundamental to preventing stress-related mucosal ulceration and its clinically important manifestation gastrointestinal bleeding.[66] Drugs commonly used for prophylaxis of SMRD include sucralfate, histamine 2-receptor antagonists (H2 blockers) and Proton Pump Inhibitors (PPIs). Enteral or intravenous administration of PPIs to critically ill patients has been shown to elevate and consistently maintain gastric pH $\geq$ 4.0. PPIs are therefore as safe and as efficacious as H2 blockers or sucralfate for prevention of bleeding from SRMD.[67,68] Sucralfate, on the other hand, can protect the gastric mucosa without raising gastric pH. The benefit of SRMD prophylaxis in all ICU patients has not been convincingly proven.[69] An increased risk of nosocomial pneumonia with use of H2 blockers and PPIs as well as of reduced absorption of concomitantly administered oral medications with sucralfate has lead several authors to recommend against routine prophylaxis against SMRD in the ICU.[69,70] There is a need to carry out a risk-benefit assessment for each critically ill medical patient prior to initiation of SRMD prophylaxis.

Pressure Ulcers

Another common problem in intensive care settings is the occurrence of pressure ulcers (previously called 'bed sores'). There is a wide variation in the reported prevalence (4 to 49%).[71] Age, duration of MV, bowel incontinence, presence of diabetes mellitus, spinal cord injury and renal failure are proven risk factors for its occurrence.[72-74] Pressure reducing devices such as special mattresses (alternating pressure air, low air loss and foam) can be used for prevention of pressure ulcers among ICU patients.[75] Enteral diet, enriched in eicosapentaenoic acid, gamma-linolenic acid and vitamins A, C and E has been associated with a significantly lower occurrence of new pressure ulcers among critically ill patients with acute lung injury.[76] Implementation of guidelines for pressure ulcer care has been shown to result in a significant and sustained decrease in the development of grade II-IV pressure ulcers in critically ill patients.[77] Timely transfer to a specific pressure reducing mattress prior to the occurrence of a pressure ulcer is the most important factor. Undoubtedly, pressure sore development is a complex phenomenon, and no single intervention can tackle the problem effectively. A multidisciplinary team approach is the most appropriate way to improve prevention as well as treatment.[78]

Airway Management

Arjun Srinivasan, Ritesh Agarwal

Airway management is an obligatory skill of critical care physicians and paramedical staff which is tested on regular basis by the susceptibility of critically ill patients to hypoxic injury when emergency intubation is required. These patients typically have varying degrees of acute hypoxemia, acidosis, and hemodynamic instability when intubation is required, and tolerate poorly any delays in establishing an airway. Essentially, the approach comprises of attempts at securing an appropriate airway in minimal time (Fig. 148.1). A systematic study of complications associated with airway management in the Intensive Care Unit (ICU) reported major complications in a significant number of patients, such as Difficult Intubations (DIs) (8%), esophageal intubation (8%), pulmonary aspiration (4%), and an associated mortality rate of 3%.[1] Respiratory failure and shock were independent predictors of complications.

Aforementioned conditions also predispose the patients to become combative during attempts at securing the airway; this in addition to inadequate knowledge of the anatomy, positioning and absence of skilled assistants is a sure recipe for disaster. Physicians who are faced with these challenges should be well versed in noninvasive bag and mask ventilation which help in preoxygenation and thus decreases the hypoxic damage as well as provides with time for sedation with or without muscle relaxation to facilitate intubation. Basic knowledge of nose, oral cavity, pharynx and larynx is necessary for successful management of airway as well as for prevention of injury to these structures.[2]

In the supine position, during unconsciousness, relaxation of the muscles supporting the airway frequently leads to upper airway obstruction. This occurs primarily at the level of the soft palate/tongue, can usually be overcome by jaw thrust, chin lift, “sniffing” position, or insertion of an oropharyngeal or nasopharyngeal airway. A number of structures may obstruct the laryngoscopist’s view of the laryngeal inlet. Mouth opening at the temporomandibular joint, oral cavity size, dental structures, and tongue size are immediately apparent as obstruction to visualization of the glottis. Furthermore, the angle at which one attempts to bring the airway entrance into view is of importance. In neutral position, the line of sight reaches the posterior pharynx, uvula and soft palate. With extension, it is possible to view the hypopharynx, the area just cephalad to the glottic opening. When the patient’s head is placed in the sniffing position (flexion of the cervical spine and extension of the atlanto-occipital joint), the axes of the airway are better aligned.[3]

AIRWAY ASSESSMENT

Critical care setting opens a Pandora’s Box in terms of difficulties not all of which can be anticipated. The principle is to determine whether patient requires non-invasive or invasive ventilatory support, once that is clear, the ease of establishment of either one needs to be assessed. In a critical care setting, a brief and focused examination to assess a patient’s airway prior to performing a potentially difficult endotracheal intubation goes a long way in influencing the strategy for airway management and the success of the procedure. If the patient needs invasive ventilatory support, the individual should quickly be assessed for difficult airway.[4] The American Society of Anesthesiologists (ASA) defines a

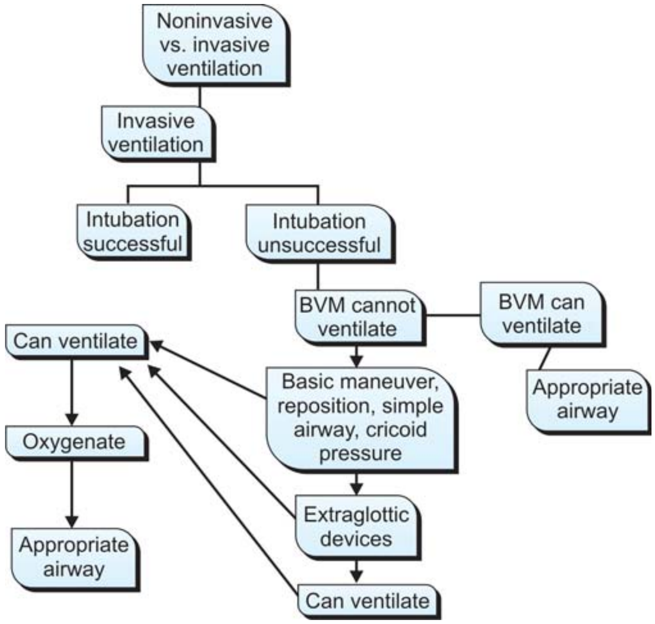

Fig. 148.1: An approach to airway management in ICU

difficult airway as: (1) difficult Bag-Value Mark (BVM) ventilation: The inability to maintain an adequate oxygen saturation greater than 90% or signs of inadequate ventilation (e.g. cyanosis, absent breath sounds or hemodynamic instability) with BVM ventilation or (2) difficult endotracheal intubation: Greater than three failed intubation attempts or failure to intubate after 10 minutes by an experienced operator.[5] Some experts also include difficult placement of extraglottis devices.

Difficult Mask Ventilation

The mnemonic, MOANS which refers to Mask seal, Obesity (BMI of >26 kg/m^2), age greater than 55 years, No teeth and a history of Snoring or Stiff lungs are risk factors associated with difficult mask ventilation in elective setting.[6] In addition to the aforementioned factors altered sensorium, sedation and use of NMBAs result in decrease in the tone of soft palate increasing airway resistance.[7] Because the soft palate rather than the tongue is the site of obstruction, ventilation is assisted by a jaw thrust or head tilt, the placement of either a nasopharyngeal or oropharyngeal airway, and the application of positive-pressure assisted ventilation. On the other hand, pooling of secretions, inadequate sedation and agitation can precipitate laryngeal spasm with similar consequence. This involuntary spasm of the laryngeal musculature may be ablated with positive-pressure ventilation, suctioning of secretions, cessation of airway manipulation, and jaw thrust. Severe instances may require neuromuscular blockade.

Difficult Intubation (DI)

Approximately 30% of critically ill individuals are fit for formal assessment. LEMON airway assessment model has recently been validated in critical care setting (Table 148.1). Of the parameters, Mallampati score was found to be most difficult to assess and large incisors, a reduced mouth opening, and a reduced thyroid to floor of mouth distance were found to be the factors associated with significant risk of difficult intubation. This calls for formulation of a protocol with fewer parameters which is easier to apply in emergency.[8]

TABLE 148.1: LEMON airway assessment model

Parameters	*Points*
Look	
1. Large incisors	1
2. Large tongue	1
3. Facial trauma	1

Difficult Use of Extraglottic Devices

In an emergency, a Laryngeal Mask Airway (LMA) can serve as the primary rescue airway in a 'cannot ventilate/ cannot intubate' scenario or can be used as a bridge or temporary airway while completing a cricothyroidotomy. The LMA is inserted above the glottis into the laryngeal space and then a cuff is inflated to achieve the proper seal. This directs air from above the vocal cords through the glottis into the trachea. A proper seal is essential to create a channel through which oxygen is routed into the trachea. The LMA is an intermediate airway (Table 148.2), allow ventilation across the larynx but do not provide complete airway control. Even though the insertion of extraglottic devices is easier than intubation, several factors (RODS) can interfere with insertion of extraglottic devices.[6] At least some access to the oral airway is necessary for placement of an extraglottic device, so the R in RODS stands for restricted mouth opening; an extraglottic device is not feasible if there is upper airway Obstruction (O); a Disrupted or Distorted airway (D); prevents an adequate seal, thereby resulting in unsatisfactory functioning of the extraglottic device. A Stiff cervical spine or Stiff lungs are the S in RODS.

TABLE 148.2: Examples of intermediate/temporary airway in an emergency

- Laryngeal airway
- Airway management device
- Cuffed oropharyngeal airway

Bag Valve and Mask Ventilation

Providing positive pressure ventilation with a facemask and a bag-valve device is a lifesaving maneuver. Facemask ventilation is used in patients who have respiratory failure but still breathing spontaneously, and in patients with complete apnea. Facemask ventilation can be indicated in any situation in which spontaneous breathing is failing or has ceased, including cardiopulmonary arrest. Though rarely contraindicated, caution needs to be exercised in the presence of facial/eye trauma or foreign body in the oral cavity which can lead to aspiration pneumonitis. Although seemingly simple, the technique requires an understanding of the airway anatomy, the equipment and the indications.

There are several types of masks available in different sizes and materials. Transparent masks allow for inspection of lip color, condensation, secretions or vomitus and are therefore generally preferred. A good fit requires conformation with the facial anatomy, several sizes therefore should be available at hand. A self-inflating bag with a non-rebreathing unidirectional valve which can be connected to the mask, constitutes rest of the equipment. The ability to deliver positive pressure can be checked by compressing the bag while blocking the outlet with the thumb. If there is resistance or if air fizzles out around the thumb, then positive pressure can be delivered. Care should be taken to ensure at hand availability of oxygen supply, suction apparatus and equipment necessary for endotracheal intubation in case of difficulty in ventilation with bag and mask.

Single-Hand Technique

The most common method used to hold the mask requires placing your thumb and index finger on the body of the mask while your other fingers pull the jaw forward and extend the head. Place your middle and ring fingers on the ridge of the mandible and the fifth finger behind the angle of the mandible.[9,10] The tongue is the most common cause of airway obstruction. It is important to minimize the pressure applied to the submandibular soft tissues because pressure may further obstruct the airway by pushing the tongue against the palate. Maintaining an adequate seal while extending the patient's head, thrusting the jaw forward, and squeezing the bag with the other hand may require considerable manual strength and coordination. Extreme caution is advised in patients with cervical spine injuries, in which flexion or extension of the neck is contraindicated. In this situation, the jaw-thrust maneuver alone, without head extension, is recommended.

Two-Hand Technique

You might find it difficult or impossible to maintain an adequate seal with only one hand. This is particularly true in the case of obese or edentulous patients or those with abundant facial hair. In these situations, hold the mask with two hands, with each hand positioned as described in the one-hand technique. A second person should compress the bag-valve device.[10] Regardless of the method used, adequacy of ventilation can be assessed by looking for chest rise and by auscultation for breath sounds. Presence of significant epigastric sounds would mean poor ventilation.[11]

Oropharyngeal or nasopharyngeal airway can facilitate ventilation in otherwise difficult to ventilate patients by overcoming the resistance offered by the soft tissues. This is especially true for obese patients and those with restricted neck mobility. Caution should be exercised while using in patients with preserved gag reflex for the fear of triggering laryngospasm. When the patient is breathing spontaneously, the delivered tidal volume needs synchronization with the patient's inspiration. Regardless of the presence of spontaneous respiratory effort, when excessive pressure is delivered to the airway, gastric insufflation may occur. This may lead to a vicious cycle of increased intra-abdominal pressure, which requires higher peak inspiratory pressures, predisposing patients to vomiting or regurgitation.[11]

Pathophysiology of Intubation

The upper airway reflexes include the glottic closure reflex (laryngospasm), cough, sneeze and swallow reflex. The function of the various upper airway reflexes is to protect the respiratory system and gas exchange surface from foreign or noxious substances. This is why there is a profusion of sensory nerve endings in the airway and rapid motor responses to any stimuli in the airway. Bronchospasm also can occur as a reflex response to endotracheal intubation even in patients who have no history of asthma or obstructive lung disease. Efferent parasympathetic fibers travel to the bronchial smooth muscle and stimulate the M3 cholinergic fibers on the bronchial smooth muscle, causing a cholinergically mediated bronchoconstriction.

In children and newborn, the vagal response to airway manipulation results in bradypnea and bradycardia. Conversely, in adults and adolescents, increased heart rate and blood pressure are the typical responses to airway manipulation.[12] This response is mediated via postganglionic cardioacceleratory nerves from the paravertebral sympathetic chain ganglia, which includes norepinephrine release from adrenergic nerve terminals and the secretion of norepinephrine from the adrenal medulla. Stimulation of the β-adrenergic nerves to the renal juxtaglomerular apparatus activates the renin-angiotensin system resulting in the release of renin, which further raises the blood pressure.

Stimulation of the central nervous system caused by activation of the autonomic nervous system leads to elevations in the cerebral metabolic rate, oxygen consumption, cerebral blood flow and intraocular pressure. This could have disastrous consequences in patients who have impaired CNS autoregulation or elevated intracranial pressure from illness or trauma.

Rapid Sequence Intubation

Rapid Sequence Intubation (RSI) is a process whereby pharmacologic agents, specifically a sedative (e.g. induction agent) and a neuromuscular blocking agent are administered in rapid succession to facilitate endotracheal intubation.[13] When a neuromuscular blocking agent is not used, it is called "facilitated intubation". Though originally described in patients undergoing elective intubation for surgery, this has become the standard of care in critical care setting notwithstanding the controversies and complications (Table 148.3).

RSI generally consists of the following seven steps:

i. Preparation

The lead up to intubation in a critically ill patient can fast deteriorate to panic and chaos if the team members are not fully aware of their respective roles. This is best established by running mock drills to identify deficiencies and assembling an intubation kit according to a preset checklist as per the ICU requirements. The essential equipment needed for intubation is Suction, Oxygen, Airway, Pharmacology, Monitoring and Equipment (SOAPME). For the airway, include the ET tubes of multiple sizes, laryngoscopes, blades, stylets and BVM. For pharmacology, select, draw up, and label the appropriate medications (sedative, neuromuscular blocker, ancillary drugs) based on the history, physical examination and equipment available. Monitoring should include pulse oximetry and cardiac monitoring at a minimum; preferably with capnography. This phase should also include a contingency plan in case of 'can't ventilate and can't intubate' scenario.

TABLE 148.3: Merits and pitfalls with rapid sequence intubation

Merits	*Pitfalls*
Prevents aspiration and its complications	Adverse effects of the drugs used
Prevents/limits physiological stress response to intubation	Convert partial obstruction to total due to loss of tone
Limits cervical spine movement in trauma patients	Crash airway resulting in cannot ventilate and cannot intubate
Decreases tracheal trauma	Hypoxia
Increases patient comfort and decreases recall	

ii. Preoxygenation

The principle consists of replacing nitrogen in the lungs with 100% oxygen so as to allow adequate time for intubation before desaturation occurs. It can be delivered by tight fitting mask or in the presence of apnea by BVM. In the absence of apnea BVM is discouraged as it can lead to gastric distention and aspiration. It is adequate to prevent desaturation for up to three mins even in the presence of apnea. Obese and hypoxic respiratory failure tends to desaturate early. Patients, who have respiratory failure as a result of underlying cardiopulmonary disease, frequently do not respond to the standard mode of preoxygenation. Only one-half of such patients had an increase in PaO_2 greater than 5% above baseline with the standard four-minute preoxygenation.[14] Better PaO_2 and pulse oximetry values were found using Noninvasive Positive Pressure Ventilation (NIPPV) than conventional preoxygenation before endotracheal intubation.[15]

iii. Premedication

It is important for prevention of negative physiological responses to intubation. This should ideally precede induction by three minutes, simultaneously with preoxygenation. Lidocaine 1.5 mg/kg, fentanyl 2 to 3 µg/kg, and atropine 0.02 mg/kg (minimum 0.1 mg, maximum 0.5 mg) are usually the drugs used. Use of these drugs is governed by the associated co-morbidities. Some general caveats to be remembered are: (a) use lidocaine and fentanyl for patients with elevated ICP and impaired autoregulation, (b) fentanyl for patients with major vessel dissection or rupture or those with significant ischemic heart disease, (c) avoid fentanyl in any patient with shock as these patients are dependent on their sympathetic drive to maintain circulation, (d) use lidocaine for patients with underlying airway obstruction, and (e) atropine is indicated for pediatric patients and in adults with significant bradycardia especially if use of succinylcholine (Sch) is being contemplated. In patients at risk for raised ICP, which may be precipitated by fasciculations which occur with the use of succinylcholine, one tenth the paralyzing dose of Non-depolarizing neuromuscular blocking agent (ND-NMB) may be given along with premedication to prevent fasciculations, example for rocuronium, the dose would be 10% of 0.6 mg/kg = 0.06 mg/kg.[16]

iv. Induction and Paralysis

The step which reduces patient discomfort, and recall as well as increases the chance of successful intubation is surprisingly, also the most controversial. Facilitated intubation refers to the use of sedative alone without paralysis. Detractors of RSI advice against the use of paralysis in case a difficult airway is anticipated. A study in the prehospital air medical setting, using 0.3 mg/kg of etomidate as the sedative without any NMB reported an 89% rate of successful intubation, difficult intubation in 16%, and episodes of clenched jaws and orofacial muscle spasm.[17] A later study from the same investigators prospectively compared facilitated intubation using etomidate vs RSI using etomidate and succinylcholine showed higher incidence of failure with use of sedative alone (63% requiring additional medication vs 4% in RSI).[18] Summarizing, the available evidence favors the use of paralyzing agent unless specifically contraindicated in an individual patient.

The choice of sedative for induction is dictated by patient characteristics as well as the physician and institutional preferences. According to the National Emergency Airway Registry (NEAR) study, the most frequently used induction agents were etomidate (69%), midazolam (16%), fentanyl (6%) and ketamine (3%).[19] Generally the dosages of the sedatives when used for induction are slightly higher than the dose used for sedation.

Etomidate: Etomidate is a nonbarbiturate hypnotic agent that is used for the rapid induction of anesthesia. This imidazole derivative has a rapid onset of action and a short half-life. The usual dose is 0.3 mg/kg or 20 mg in a 70-kg adult. It is often used in trauma patients with known or potential bleeding, hypovolemia, and in patients with limited cardiac reserve, because it does not have significant cardiovascular effects. Etomidate also decreases intracranial pressure (ICP) and the cerebral metabolic rate, which suggests that it may have a neuroprotective effect. In patients of septic shock, the use of etomidate for induction has shown worse outcome.[4,20] This is attributed to inhibition of 11-β-hydroxylase, an enzyme necessary for adrenal steroid production. Myoclonus is another side effect of etomidate that may interfere with intubation if a paralytic agent is not used.

Benzodiazepines: Midazolam is the most commonly used benzodiazepine. It scores over diazepam in being short acting with fewer adverse effects, better amnesia and greater potency. Usual dose for induction is 0.5 to 1.5 mg/kg. This class of drugs has sedative, hypnotic, amnestic, anxiolytic, muscle relaxant and anticonvulsant properties. Negligible cardiovascular effects are an added advantage but significant disadvantages include respiratory depression and apnea. Other uncommon side effects are paradoxical agitation, vomiting, coughing and hiccups.

Barbiturates: Thiopental is the most commonly used drug in this group. Thiopental decreases both cerebral blood flow and the metabolic demands of the brain, which make it an ideal sedative agent in patients with known increased ICP or patients with head injury who are hemodynamically stable. Dose for induction is 3 to 4 mg/kg. Its negative inotropic effect precludes its use in patients with underlying heart disease as well as in the presence of shock. The role of thiopental as an induction agent in critical care setting is limited to hemodynamically stable patients.

Propofol: Propofol is a rapid onset ultra-short-acting sedative hypnotic agent. It has antiemetic properties, but no analgesic effects. It needs no dose modification in the presence of hepatic or renal dysfunction. Side effects include hypotension, bradycardia, hypoxia and apnea, so it should be administered slowly. Propofol also has negative cardiovascular effects so it should be used with caution in patients with volume depletion, hypotension or cardiovascular disease. Because of these side effects/ complications, its use as a sedative for RSI is limited in critically ill patients.

Ketamine: Ketamine, a dissociative anesthetic, exerts its effects by interrupting the connection between the thalamo-neocortical tracts and the limbic system. Unlike all the other sedatives, it has analgesic properties. Ketamine's sympathomimetic effects increase the heart rate, blood pressure, and cardiac output making it an excellent sedative in patients who are hypotensive, especially if secondary to shock, hemorrhage, dehydration, pericarditis or tamponade. However, these sympathomimetic effects are undesirable in patients who already have significant hypertension or tachycardia. Ketamine also causes an increase in ICP by both an increase in systemic blood pressure and cerebral vasodilatation and, therefore, contraindicated in patients with ICP, intracerebral hemorrhage, intracranial mass or head trauma.

Ketamine, through the release of endogenous catecholamines, relieves bronchospasm by dilating bronchial smooth muscles and stimulating the pulmonary β-receptors making it ideal for use in known asthmatics. Ketamine increases tracheobronchial/ oropharyngeal secretions. This can be counteracted with concomitant use of glycopyrrolate or atropine. Use of ketamine has been associated with emergence of reaction which can be disconcerting for the patient.

Paralysis: Once the appropriate sedative is administered, the choice of agents for paralysis is not wide. Neuromuscular Blocking agents (NMBs) are substances that paralyze skeletal muscles by blocking nerve impulse transmission at the neuromuscular junction. Patients given NMB may be aware of their environment, including painful stimuli, even though they are unable to respond. Failure to sedate the patient allows the possibility of negative physiologic responses to airway manipulation such as increased ICP, hypertension and tachycardia. Above all, it is prudent to avoid an ordeal which can be remembered and recalled. All NMBs are structurally similar to the neurotransmitter acetylcholine. They are broadly divided into depolarizing and non-depolarizing NMBs.

Depolarizing neuromuscular blocking agents (succinylcholine): Succinylcholine is the only depolarizing neuromuscular blocking agent currently licensed for use. It acts by binding to the Acetylcholine Receptor (AchR) on the motor endplate, causes depolarization of the postjunctional neuromuscular membrane, resulting in continuous stimulation of the motor endplate AchRs. The initial depolarization manifests a fasciculation all over body and helps an astute clinician to time the onset of paralysis. The action is terminated when the drug unbinds from AchR and diffuses back to circulation where it is hydrolyzed by plasma cholinesterase. It has rapid onset of action occurring within 45 to 60 seconds and short duration lasting only 6 to10 minutes. Actual body weight needs to be used for calculating the dose even in extreme conditions (BMI at either end of spectrum) with a tendency to overdose; inadequate paralysis would hinder chances of successful intubation. A dose of 1.5 mg/kg or 100 mg for an adult patient of around 70 kg is generally used; repeated doses should not be used since bradycardia and hypotension can occur secondary to vagal potentiation; multiple doses may also lead to desensitization blockage, whereby the neuromuscular membrane returns to the resting state and becomes resistant to further depolarization with Sch.

Absolute contraindications to use of succinylcholine consist of a history of malignant hyperthermia in the patient or family and high risk of severe hyperkalemia. Others adverse reactions include bradycardia, and prolonged neuromuscular blockade lasting for 6 to 8 hours after a single dose in patients with aberrant pseudo cholinesterase, raised ICT and IOP, masseter spasm and fasciculation.

Non-depolarizing neuromuscular blocking agents: Non-depolarizing (ND) NMBs competitively block Ach transmission at the postjunctional cholinergic nicotinic receptors. Unlike Sch, which causes a conformational change in the Ach receptor resulting in depolarization of the neuromuscular junction, the non-depolarizing NMB prevents Ach from access to the nicotinic receptor, thereby preventing muscle contraction. They do not cause fasciculations. Based on duration of action, NMB are classified into ultra-short acting (less than 10 minutes), short acting (10 to 20 minutes); intermediate (20 to 50 minutes); and long acting (greater than 50 minutes). Currently, there are no clinically approved ultra-short-acting ND-NMB blockers. Vecuronium, rocuronium, atracurium, and cisatracurium are intermediate acting, rocuronium is the most commonly used agent followed by vecuronium.

Currently the only rapid onset and ultra-short acting NMB available is Sch, doubling the dose of rocuronium from 0.6 mg/kg to 1.2 mg/kg decreases the onset of action to 55 seconds. Sch creates superior intubating conditions when compared to rocuronium. Current indications for use of ND-NMB are: (a) for muscle relaxation, if Sch is contraindicated or unavailable, (b) to maintain postintubation paralysis, and (c) as a pretreatment agent to lessen or eliminate the fasciculations.

v. Positioning and Protection

The aim of position is to align oral, pharyngeal and laryngeal axis along a straight line for easy visualization of cords, the same is usually achieved by 'sniffing position' when there is flexion at neck and extension at head. The position is easy to accomplish by placing a pillow or a folded towel behind the occiput. Prevention of aspiration of gastric contents is achieved by cricoid pressure classically referred to as Sellick's maneuver. The correct performance involves the use of the thumb and index or middle finger to apply firm downward pressure on the cricoid cartilage anteroposteriorly. There are data to suggest that cricoid pressure may worsen the degree of laryngeal exposure.[21-23] This is why there have been instances of regurgitation and aspiration in spite of appropriate use of cricoid pressure. Furthermore, cricoid pressure may cause unwanted significant increases in the heart rate and blood pressure. Therefore, the effectiveness of Sellick's maneuver is currently suspected but would be prudent to give cricoid pressure initially with an immediate decision to terminate the same if there is a compromise of laryngeal view.

vi. Intubation

The operator needs to position the body so that the eyes are far enough from the patient to maintain binocular vision. While holding the laryngoscope in left hand, the patient's mouth is opened with right hand and the laryngoscope blade is inserted to the right of the patient's tongue. Gradually, the blade is moved to the center of the mouth, pushing the tongue to the left. Slowly, the blade is advanced and the epiglottis is identified. Ideal placement of the laryngoscope blade depends on whether a curved or a straight blade is used. When using a curved blade, the tip is placed into the vallecula epiglottica, between the base of the tongue and the epiglottis; and posterior to the epiglottis if a straight blade is being used. With the tip of the blade correctly positioned, the laryngoscope is lifted upward and forward at a 45° angle with adequate care to ensure axis of the laryngoscope's handle, in the direction of the ceiling and not at wrist as that would not only cause poor visualization but also risk dental and soft tissue injury.

Appropriate size endotracheal tube should be ready with the cuff checked for leakage and stylet in situ.[24] Sizes between 7.5 to 8.5 are appropriate for most adults. Stylet should not extend beyond the tip of the tube and the shape of stylet tube combination may be manipulated for easier insertion. With the tube in right hand and clear view of the cords, the tube is inserted into the right side of the patient's mouth. Care must be taken to ensure that the tube does not obstruct the view and the tube is passed until the balloon disappears into the trachea. The stylet is removed at this point and the tube is further advanced till the balloon is 3 to 4 cm beyond the cords. The position is at around 21 cm for females and 23 cm for adult male. The cuff is inflated to a pressure 15 to 25 cm of water required to prevent air leak. The gold standard for confirming the tracheal position of tube is bronchoscopy, but for practical reasons auscultation for equal breath sounds or capnography would suffice.[24]

vii. Management of Crash Airways

Clinician is likely to encounter this situation from time-to-time regardless of the theoretical knowledge, and wealth of experience. Recognition, time management and immediate call for help are key factors that determine the outcome in such situations. Options are a bridge to tide over the crisis situation in form of extraglottic devices or immediate surgical airway according to available infrastructure, ICU protocol and clinical expertise. Laryngeal mask airway is the most commonly used of the myriad of devices. It is a bridge to ensure ventilation when a secure airway is being planned. There are very few reports of failure to secure airway with LMA,[25] hence is recommended by American Society of Anesthesiologist Task Force guidelines for management of difficult airway as the rescue strategy of choice in case of failed airway.[5]

Cricothyroidotomy is an emergency surgical procedure done on patients with failed airway or in whom attempt at securing airway is deemed too risky. The procedure involves making an incision in the cricothyroid membrane, which lies between the thyroid and cricoid cartilages, and inserting a tracheostomy tube into the trachea to allow ventilation. Whenever possible, cricothyroidotomy should be performed by physicians fully trained and skilled in carrying out the procedure, such as the emergency physicians, surgeons and intensivists.[26-28] The only contraindications are massive laryngeal trauma and when intubation is a viable option. Local area preparation involves cleaning and draping. Tracheostomy tube of internal diameter of 6 mm is ideal and can be inserted with ease when compared to a larger tube. A tracheostomy tube placed during a cricothyroidotomy performed under emergency conditions can be left in place for up to 72 hours. Because of the potential complications of cricothyroidotomy (such as subglottic stenosis and damage to the thyroid and cricoid cartilages), it should be converted to a tracheostomy if airway access is needed for more than 72 hours.

Complex Airways Diseases

Rubal Patel, Ann L Rutt, Arthur Sung

INTRODUCTION

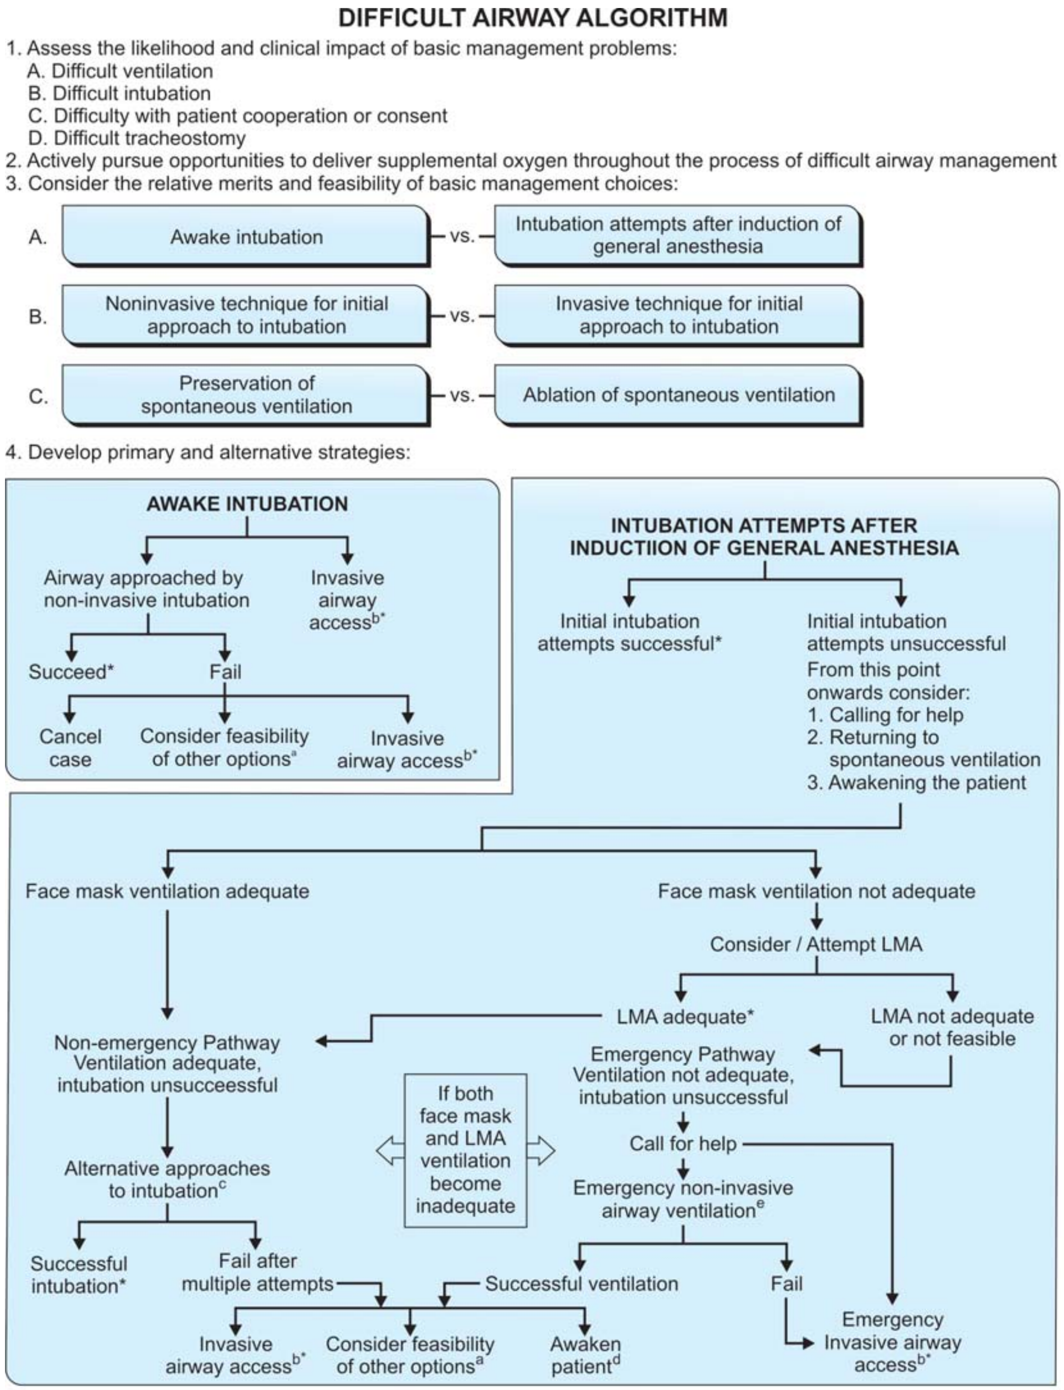
The intensive care unit presents many challenging conditions that require expert knowledge of complex airway management. In the acutely decompensating patient, securing the airway in a timely manner with the best practice approach is critical to ensuring an optimal outcome. The initial evaluation should include historical, clinical and anatomic components in order to consider important factors, such as the neurological status, level of consciousness, hemodynamic status and respiratory reserve. Soliciting assistance from other disciplines with airway expertise is paramount when confronted with a difficult airway. Anesthesiologists, surgeons and otolaryngologists are colleagues, who can offer vital and unique skills to rescue a dire scenario.

The difficult airway is defined as "the clinical situation, in which a conventionally trained anesthesiologist experiences difficulty with mask ventilation of the upper airway, tracheal intubation, or both".[1] Failure to recognize risk factors and inadequate management of the difficult airway usually results in adverse events, such as airway injury, hypoxic brain injury and even death.[2,3] Therefore, in the Intensive Care Unit (ICU) setting, intensivists should be familiar with the equipment and techniques to maintain and secure the airway. Even the most experienced clinician, however, will encounter difficulties with airway management. This chapter aims to discuss comprehensive management of the difficult airway, with a focus on the intensivist and the ICU as the reference environment.

Definition of a Difficult Airway

The difficult airway can be classified into two scenarios, difficult mask ventilation and difficult tracheal intubation. Difficult mask ventilation occurs, when there is inability to maintain oxygen saturation above 90%. Difficult tracheal intubation occurs, when multiple attempts at endotracheal intubation are unsuccessful. The incidence of airway trauma and edema increase and ultimately create a critical airway scenario, such as "cannot ventilate-cannot intubate" when attempts at endotracheal intubation are repeated three or four times.

Difficult intubations are reported in 1.5 to 8.5% of airway emergencies and impossible tracheal intubation occurs in up to 0.5% of the population.[3] Complication rates in the ICU environment are higher than in a controlled setting, such as the operating room due to the limited physiologic reserve and comorbidities of patients. Furthermore in the ICU setting, a thorough evaluation of anatomy may not be adequately performed. Difficult intubations can arise from difficulty in visualization of the larynx or anatomic abnormality (distortion or narrowing of the larynx or trachea). Therefore, implementation of training programs for ICU staff, immediate access to advanced airway devices and knowledge and incorporation of the American Society of Anesthesiologists (ASA), Difficult Airway Algorithm[1] (DAA) (Fig. 149.1) may decrease the incidence of serious complications related to airway instrumentation in the ICU.



DIFFICULT AIRWAY ALGORITHM
1. Assess the likelihood and clinical impact of basic management problems:
A. Difficult ventilation
B. Difficult intubation
C. Difficulty with patient cooperation or consent
D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:
A.
Awake intubation
vs.
Intubation attempts after induction of general anesthesia
B.
Noninvasive technique for initial approach to intubation
vs.
Invasive technique for initial approach to intubation
C.
Preservation of spontaneous ventilation
vs.
Ablation of spontaneous ventilation
4. Develop primary and alternative strategies:
AWAKE INTUBATION
Airway approached by non-invasive intubation
Invasive airway access[b*]
Succeed*
Fail
Cancel case
Consider feasibility of other options[a]
Invasive airway access[b*]
INTUBATION ATTEMPTS AFTER INDUCTIION OF GENERAL ANESTHESIA
Initial intubation attempts successful*
Initial intubation attempts unsuccessful
From this point onwards consider:
1. Calling for help
2. Returning to spontaneous ventilation
3. Awakening the patient
Face mask ventilation adequate
Face mask ventilation not adequate
Consider / Attempt LMA
LMA adequate*
LMA not adequate or not feasible
Non-emergency Pathway Ventilation adequate, intubation unsucceessful
Emergency Pathway Ventilation not adequate, intubation unsuccessful
If both face mask and LMA ventilation become inadequate
Call for help
Emergency non-invasive airway ventilation[e]
Alternative approaches to intubation[c]
Successful intubation*
Fail after multiple attempts
Successful ventilation
Fail
Invasive airway access[b*]
Consider feasibility of other options[a]
Awaken patient[d]
Emergency Invasive airway access[b*]

*** Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2**

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask Ventilation will not be problematic. Therefore, there options may be of limited value if this step in the aligorithm has been reached via the emergency pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation,condait (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde Intubation, and blind oral or nasal intubation,

d. Consider re-preparation of the patient for awake intubation or cancelling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

Fig. 149.1: Illustrative outline of practice guidelines for management of the difficult airway (difficult airway algorithm") formulated by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway[1]

TABLE 149.1: Indications for endotracheal intubation

Cardiopulmonary arrest
Ventilatory support (hypoxemic or hypercarbic respiratory failure)
Inability to protect airway (altered mental status, head injury, drug overdose)
Airway obstruction (malignancy)
Inhalational injury (burns)
Protection from aspiration (secretions, blood)
General anesthesia (surgery, rigid bronchoscopy)

Indications for Artificial Airway (Table 149.1)

Establishing the indication for intubation is the initial step in any airway management algorithm. Regardless of the underlying cause, restoring adequate oxygenation and ventilation is of greatest importance. Indications for endotracheal intubation include:

1. Hypoxic or hypercapnic respiratory failure
2. Inability to protect the airway due to neurologic insults, such as stroke or drug overdose
3. Airway obstruction from malignancy or benign causes
4. Inability to clear secretions, blood or foreign material.

Three principal modalities are available for the delivery of mechanical ventilation to a critically ill patient. These are Noninvasive Positive Pressure Ventilation (NIPPV) via facemask, extraglottic airway and the endotracheal route. The use of NIPPV has shown benefit in specific clinical situations, such as acute exacerbations of obstructive airway disease or cardiogenic pulmonary edema.[4] However, its use in noncardiogenic respiratory failure remains unclear.[5] In addition, NIPPV is contraindicated in various situations, where patients have depressed mental status and copious secretions. Consequently, endotracheal intubation remains the mainstay of mechanical ventilatory support in the intensive care unit and will be the primary topic of this chapter.

Training Strategies

Proficiency in airway management is achieved through various educational tools. Knowledge of normal airway anatomy and its variants is essential to assess for the type of intubation approach and to predict the level of difficulty that may be encountered during the procedure. Airway models and virtual simulators are essential tools to teach trainees basic information regarding airway intubation and equipment without direct patient contact. Performing procedures on patients under the direct supervision of experienced mentors is paramount to accrue experiences that cannot be duplicated with training models. Advancement through the training process should be a stepwise approach, with graded responsibilities and always under appropriate mentorship.

It is essential to understand that airway management is a multidisciplinary skill. Requesting assistance and consultation with other disciplines should always be encouraged. General and thoracic surgeons, otolaryngologists, anesthesiologists and interventional pulmonologists are invaluable members of an airway team. Other team members include, nurses at the bedside and respiratory therapists. Their training and knowledge complements the skill set of the clinician. Communication with the entire team is paramount, when dealing with complex airway issues.

ANATOMY

A key component to competency in complex airway management is familiarity and understanding of airway anatomy. The airway is divided into the upper (nares to glottis) and lower (trachea and conducting bronchi) airway (Fig. 149.2).[6,7]

Upper Airway

Evaluation of the patient for endotrachial intubation begins with examination of the oral cavity and the pharynx. The oral cavity (teeth, tongue, hard and soft palate) is assessed for clues that may impede a smooth

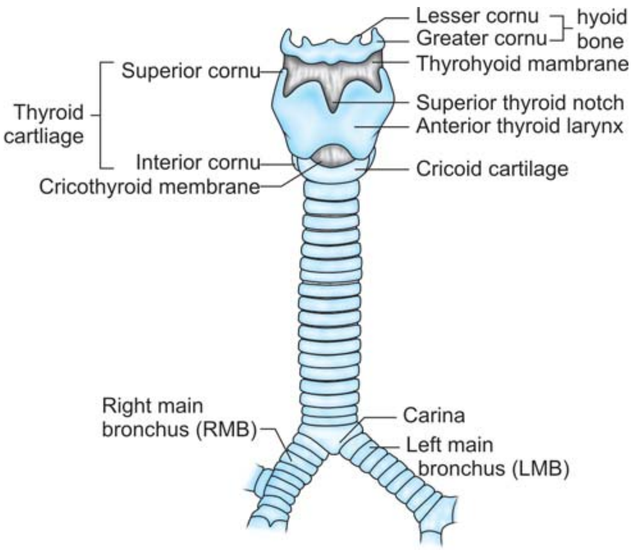


Fig. 149.2: Anatomy of the upper and lower airways. The upper airway is represented by structures above the glottic opening and the lower structure below the vocal cords[5] (Grillo)

intubation process. The tongue lies on the floor of the mouth, is attached to the hyoid bone and innervated by the hypoglossal or cranial nerve XII. The tongue commonly becomes obstructive during intubation. The roof of the mouth is comprised of the hard and soft palate. The posterior margin of the soft palate terminates at the uvula, a midline structure which assists in closing the nasopharynx during swallowing.[8]

The pharynx is divided into the nasopharynx, oropharynx and the hypopharynx. The nasopharynx lies above the soft palate and posterior to the nasal cavities. The oropharynx is inferior to the soft palate, posterior to the mouth and above the hyoid bone (Fig. 149.3).[8,9] Inferior to the oropharynx is the hypopharynx, surrounded by three constrictor muscles and three inner longitudinal muscles that are responsible for swallowing.[10] Traumatic intubations may lead to complications, resulting in dysfunctional swallowing. This area, innervated by the glossopharyngeal and vagus nerves contains the piriform recess, postcricoid region and the posterior pharyngeal wall.[6] The piriform recess is, where the tip of the laryngoscope blade rests during intubation. Due to its rich innervation, adequate topical anesthesia is essential, to prevent excessive cough and discomfort. The hypopharynx terminates at the cricoid cartilage and is separated from the larynx by the epiglottis.

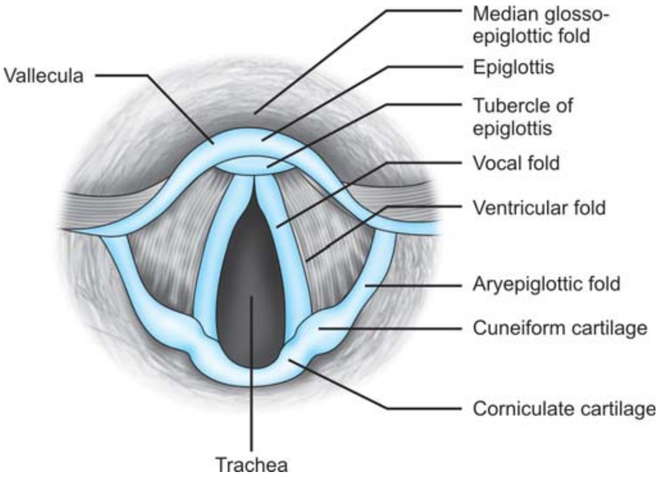

Fig. 149.4: Anatomy of the vocal cords

Wikipedia contributors. "Vocal folds." *Wikipedia, The Free Encyclopedia*. Wikipedia, The Free Encyclopedia, 5 Jun. 2010. Web. 14 Jun. 2010

The larynx located at the level of the third to sixth cervical spine, is inferior to the hyoid bone and superior to the trachea and comprised of nine cartilages. Three of the cartilages are unpaired: The thyroid, the cricoid and the epiglottis and three are paired: The corniculates, the cuneiforms and the arytenoids (Fig. 149.4). The cartilaginous structures are potential sites for trauma and may result in dislocations and injuries. The space between the base of the tongue and the anterior surface of the epiglottis on either side is called the vallecula. The vallecula is a potential harbor for foreign bodies, such as food particles, which can cause upper airway obstruction.[6] The thyroid cartilage is attached to the cricoid, by the cricothyroid membrane, measuring 0.9 x 3.0 cm in the adult. This thin membrane is near the surface of the skin, relatively avascular and serves as the landmark for an emergent cricothyroidotomy. Ligaments and laryngeal muscles attach the cricoid cartilage to the tracheal rings.

The laryngeal muscles that are responsible for opening and closing the glottis are the lateral cricoarytenoid (adduction), the posterior cricoarytenoid (abduction) and the transverse arytenoids. Proper anesthesia and relaxation of these muscles needs to be achieved, to allow adequate glottic opening. The cricothyroid, vocalis and the thyroarytenoid are muscles that control the tension of the vocal ligaments.[11] Injury to this area can cause laryngeal nerve damage, which can lead to tensing of the vocal cords and airway closure.[12] The distal portion of the upper airway is the glottis, comprised of the true and false vocal cords and the rima glottidis (opening between the true cords). The glottis is the narrowest point in the airway in persons over 8 years of age, while the cricoid cartilage is the narrowest point in the infant airway.

Lower Airway

The lower airway is comprised of the trachea and conducting bronchi. The trachea is a fibrous, muscular tube that extends approximately 10 to 12 cm in length and 2 cm in width in the adult, from the cricoid cartilage to the carina.[13] Sixteen to twenty U-shaped cartilages support the trachea (rings facing anteriorly), which bifurcates at the carina into the right and left mainstem bronchus. The right mainstem bronchus is approximately 2.5 cm long, with a takeoff angle of 25° to the right upper lobe. The left mainstem bronchus is approximately 5 cm long with a takeoff angle of 45° to the left upper lobe.[11]

Tracheal Blood Supply

Branches of the inferior thyroid artery provide blood supply to the upper trachea and bronchial arteries supply the lower trachea. Vascular perfusion to the trachea may adversely affect critically ill patients with hypotension. Pressure trauma from the endotracheal cuff may result in ischemic necrosis in these situations (Fig. 149.5).[14]

Preintubation Assessment

Several factors need to be optimized prior to attempting intubation. Preparation for an unforeseen complication should be considered. Environmental conditions, patient features, such as past medical history and airway anatomy should be assessed, in order to allow for an uneventful intubation.

Environment

The physical environment should be carefully assessed, when examining a patient with respiratory distress. A general medical ward is not as well stocked with intubation tools as is the intensive care unit, while the operating room offers the most controlled environment. The environment should be altered, to make it as conducive as possible to administer care to the patient. Personnel should be limited to essential providers and spectators should be asked to leave. A cogent and concise history should be obtained from the primary care provider, nurse and family members. A recent witnessed aspiration event, for example, should alert the clinician to be aware of significant secretions and foreign materials in the upper airway. A traumatic fall, involving the cervical spine should prompt stabilization of the neck. If an artificial airway is required after potential cervical injury, hyperextension of the neck should be avoided and special techniques should be performed to avoid further injury.

In the intensive care unit, the conditions for intubation should be as close to ideal as possible. Adequate personnel, optimal patient positioning, proper lighting and the necessary equipment for endotracheal intubation should be readily available. A supply of 100% oxygen, a well fitting mask with attached bag-valve device, suction equipment, oral and nasal airways should be available prior to attempting intubation. Different instruments needed for intubation are shown in Table 149.2. The bed should be positioned with the head of the patient at the level of the physician's midchest.

Stylets

Patient Factors

It is imperative for the experienced practitioner to consider comorbidities, in predicting problems that may be encountered during endotracheal intubation. A history of a previous difficult intubation is the best predictor of a challenging airway.[11] The American Society of Anesthesiologists Task Force on Management of the Difficult Airway has developed practice guidelines, to facilitate the management of the difficult airway and to reduce the incidence of adverse outcomes, which include but are not limited to death, brain injury, cardiopulmonary arrest, unnecessary tracheostomy, airway trauma and damage to teeth.[15]

Congenital and Genetic Considerations

Individuals with dwarfism or trisomy 21 may have atlanto-axial instability and may be at risk for spinal cord injury, during attempts at endotracheal intubation. Congenital anomalies, such as Pierre Robin syndrome, Treacher Collins syndrome or Goldenhar syndrome may also present a challenge to airway management due to craniofacial abnormalities.[11]

Acquired Disease Considerations

A dry cough, hoarseness, stridor or wheezing may be suggestive of a tumor, causing intrinsic or extrinsic compression of the trachea or tracheal deviation. Disease states, such as arthritis, cervical disk abnormalities, diabetes mellitus and scleroderma impact on neck and mandibular mobility making it difficult to properly position the patient for intubation. In addition, previous surgery, burns or radiation to the neck may cause scarring and contractures, which may limit tissue mobility. The presence of a tracheostomy stoma or a scar from a previous tracheostomy may be suggestive of subglottic stenosis or an indication of a previous airway complication.

Morbidly obese individuals may have a history of snoring and obstructive sleep apnea due to a short, thick neck and excessive soft tissue of the neck and upper airway, which will consequently complicate endotracheal intubation. Insertion of the laryngoscope may also be more difficult in obese individuals. Pregnancy may also increase the risk of aspiration and bleeding from swollen oral mucosa. Infections in the mouth, salivary glands, tonsils or pharynx may cause pain, swelling or muscle spasms and limit one's ability to easily intubate. Persons with acromegaly may have enlargement of the tongue, epiglottis and vocal cords causing a narrowed glottic opening.[11]

Traumatic Injuries

A history of recent trauma may trigger suspicion of an intracranial injury, a basilar skull fracture or injury to the airway or cervical spine.

Physical Examination

A thorough inspection of the patient's posture, habitus, face, mouth, neck and jaw is essential prior to undergoing endotracheal intubation, if possible. This should be performed by careful examination from the front and side of the patient, with the individual looking forward, mouth open and tongue protruded, followed by mouth closed and neck extended.[16]

Inspection

In 1983, Dr Mallampati devised a trifold classification system of the oropharynx, to predict endotracheal intubation difficulty (Fig. 149.6). The open mouth is examined with the head in neutral position and the tongue protruded. The distance between the base of the tongue to the uvula, soft palate and pharyngeal pillars is rated:[17]

Class I:	Uvula, soft palate and pharyngeal pillars are easily visible
Class II:	Soft palate and pharyngeal pillars are visible
Class III:	Soft palate alone is visible

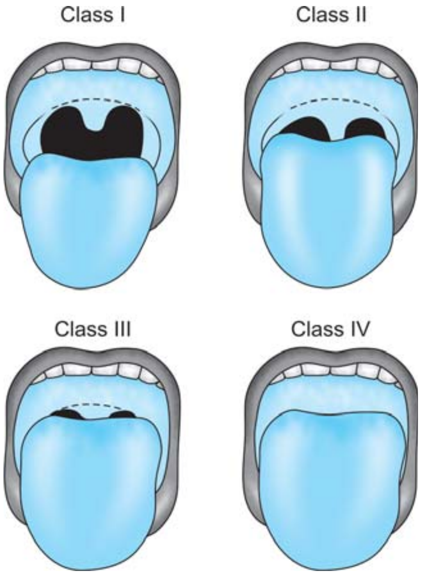

Fig. 149.6: Mallampati classification **(Mallampati)**[12] **(Sampson)**[13]:

Class I: Uvula, soft palate and pharyngeal pillars are easily visible
Class II: Soft palate and pharyngeal pillars are visible
Class III: Soft palate alone is visible
Class IV: Only hard palate is visible

An additional category, Class IV (only hard palate is visible) was later added by Sampson and Young.[18]

In addition to examining the oropharynx, the opening of the mouth and thyromental distance (distance from the mandibular mentum to the superior thyroid notch during neck extension) should be assessed. A mouth opening of less than 2 finger widths and a thyromental distance less than 3 finger widths is suggestive of a difficult airway.[19,20] An alert patient should be able to touch chin to chest, hyperextend their head and turn their head from side to side without pain or paresthesia.[11] Cervicooccipital extension of less than a 160° angle at the hyoid bone limits proper positioning of the mouth and pharynx, to visualize the glottis for endotracheal tube placement. A careful assessment of the mouth should also include evaluation for any prominent or protruding teeth, which may block the view of the glottis. The presence of loose teeth, caps and bridges add to the risk of aspiration from dislodgement or damage to the teeth.[16]

Palpation

The hyoid bone, superior thyroid notch and cricothyroid ligament should be palpated prior to attempting intubation. The neck should also be palpated for evidence of thyroid enlargement or masses, which could potentially obstruct the airway or impede visualization of the glottis.[16]

Auscultation

Auscultation of the neck and chest for stridor or adventitious breath sounds is also an important component of the preintubation assessment. The use of bronchodilators or steroids may be indicated, if airway obstruction is suspected.

Techniques

Airway management may be achieved by definitive or nondefinitive methods.[2] The nondefinite techniques include, utilization of assist devices, such as an oral or nasal airway or the Laryngeal Mask Airway (LMA). The definite methods enable control of ventilation, administration of high levels of oxygen and protection against aspiration. There are three major methods of obtaining a definitive airway: Orotracheal, nasotracheal and the surgical airway.

Bag Valve Mask

Prior to endotracheal intubation, the use of a hand-held bag valve mask to ventilate a patient should be attempted. The bag valve mask is designed to manually provide positive pressure ventilation directly or via an adjunct, such as a pocket mask. The device is capable of self-inflating and drawing in ambient air or oxygen supplied from a tank. After hyperextending the neck, to open the airway or inserting an oropharyngeal airway, the mask is placed over the nose and mouth and held firmly in position with the index finger and thumb. The remaining fingers should keep the jaw tilted upward. The other hand is used to compress the bag once every 5 s. Expert skill and knowledge of the proper use of a bag valve mask is essential.

Oral Airway

An oral airway is an important adjunct tool that may be used prior to intubation, to prevent the tongue from obstructing the airway. There are a variety of oral airways of various sizes to maintain upper airway patency (Fig. 149.7). Insertion of an oral airway is only possible, when the patient does not have a gag reflex due to altered mental status or sedation.[21]

Nasopharyngeal Airway

A nasopharyngeal airway is an alternative airway that may be used when insertion of an oral airway is difficult or impossible. It is a soft plastic or rubber tube (Fig. 149.8) that provides airflow from the nares to the pharynx. Unlike an oral airway, it can be used in conscious patients, who have an intact gag reflex.

Laryngoscopy

The most commonly practiced technique for endotracheal intubation is direct laryngoscopy. A laryngoscope is used to obtain a view of the vocal folds and the glottis. There

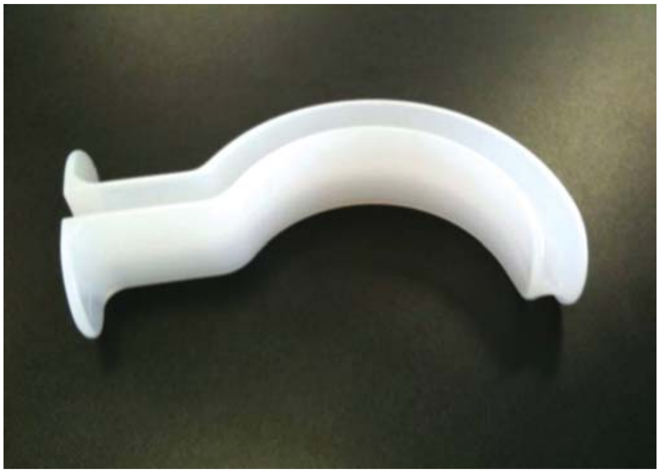

Fig. 149.7: An oral airway

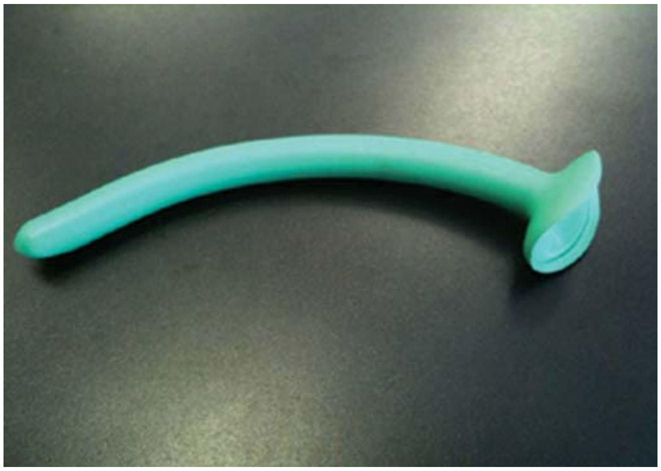

Fig. 149.8: A nasopharyngeal airway

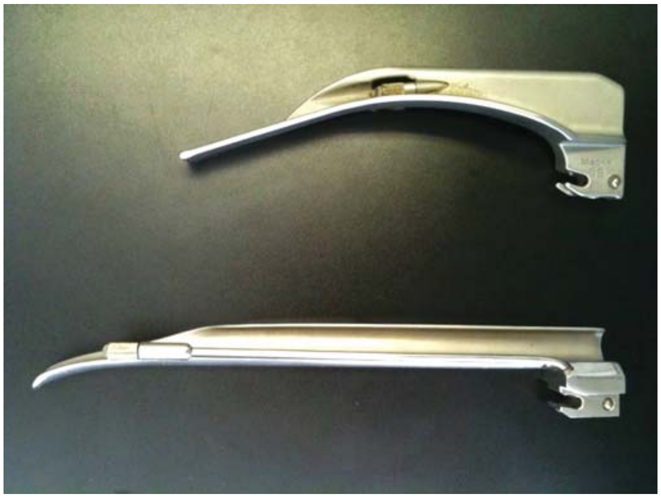

Fig. 149.9: Types of laryngoscope blades. Top: the curved Macintosh. Botttom: the straight Miller blade

are two standard types of laryngoscope blades: The curved Macintosh and the straight Miller blade (Fig. 149.9). The choice of blade shape is a matter of personal preference. The tip of the curved blade is placed in the vallecula. The tip of the straight blade should be placed posterior to the epiglottis, pinning the epiglottis between the base of the tongue and the straight blade. The handle of either laryngoscope should be pulled forward at a 45° angle, to allow visualization of the epiglottis.

The Endotracheal Tube

The standard single-lumen Endotracheal Tube (ETT) (Fig. 149.10) is a sterile tube, made of clear polyvinyl or silicone, to protect the delicate mucosal tissue and allows confirmation of tube placement due to the condensation of expired gases. The distance from the distal tip is indicated in centimeters. A radiopaque stripe or a tip marker is present, to aid in locating the tube on the chest radiograph. Most adult endotracheal tubes have a low pressure cuff system that creates a seal between the endotracheal tube and the trachea, in order to prevent aspiration from the pharynx into the lungs as well as allowing positive pressure ventilation. Ideal cuff pressure is between 18 and 25 mm H_2O when properly inflated. Under inflation of the cuff may result in tube migration, aspiration of upper airway secretions and contribute to ventilator-associated pneumonia.[22] On the other hand, inflation of the cuff above 25 mm H_2O may cause short-term mucosal ischemia and long-term tracheal stenosis due to pressure trauma.[23] Daily confirmation with a bedside cuff pressure gauge is recommended, in order to avoid cuff-related complications.[24]

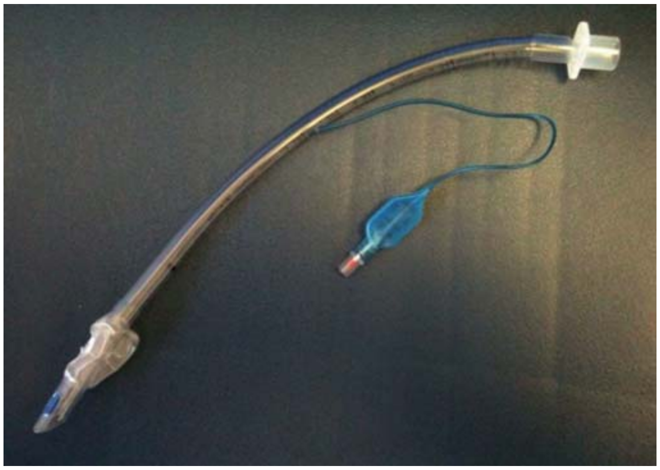

Fig. 149.10: An endotracheal tube

The selection of the endotracheal tube should be approximately 7.0 to 7.5 mm in diameter for an average adult female and 7.5 to 8.0 mm for an average adult male. Complications of endotracheal intubation include trauma, such as perforation or laceration of the pharynx, larynx, trachea or the esophagus. Specific vocal cord injury includes dislocation of the arytenoid cartilages.[25] Malpositioning of the ETT includes mainstem bronchus intubation, causing contralateral lung atelectasis and should be readily identified on physical exam and chest radiograph. Examples of other complications occurring during the peri-intubation period include, aspiration pneumonitis, hypotension, arrhythmias, hypoxia, hypercarbia, laryngeal spasm, bronchospasm and adverse events from anesthesia.[3,19]

Orotracheal Intubation

Orotracheal intubation is the most commonly performed procedure to secure an airway. The approach to the patient without a patent airway begins with removal of possible obstruction. Since the tongue is the most common cause of airway obstruction, relief is attempted by head tilt, chin lift or jaw thrust maneuvers.[25] This will decrease the amount of soft tissue obstruction around the airway. Supplemental oxygen should then be given via facemask or nasal cannula. The patient should be positioned in the sniff position, usually accomplished by placing a small rolled towel underneath the patient's head. The head of the patient should be at the level of the physician's midchest. The oropharynx should be suctioned immediately prior to intubation. The laryngoscope light and the ETT cuff are tested for illumination and proper cuff inflation respectively. The patient's upper incisors should not be used as the fulcrum for the laryngoscope.

The blade of the laryngoscope should be placed in a sweeping motion across the tongue, displacing it to allow the tip of the scope, to advance to the proximal aspect of the epiglottis. When using a Macintosh blade, the tip is placed at the valleculae and a subsequent lifting motion should maximize the view of the glottic opening. The ETT is inserted with the tip visualized going through the glottis without significant resistance. The ETT distance is noted at the level of the teeth and connected to a colorimetric capnography device, to verify appropriate placement in the airway. It is stabilized with tape or a securing device, after auscultation confirms bilateral lung aeration.

Nasotracheal Intubation

Nasotracheal intubation provides another definitive route of securing an airway, particularly in the setting of oral trauma. It may be blindly placed by inserting the tube in the nose, against the nasal septum with the curvature of the tube along the larynx, until it is visualized in the oropharynx. With the aid of a laryngoscope and Magill forceps, the tube is advanced through the glottic opening. Alternatively, the nasal tube may be inserted over an intubating bronchoscope. Nasal intubation is contraindicated in patients with basilar skull fractures and in apneic patients. Complications that can occur with this type of intubation include epistasis, laryngospasm and damage to the turbinates, nasal perforation and sinusitis.[26, 27]

TABLE 149.3: Confirmation of the endotracheal tube (ETT)

Direct visualization of the ETT passing through the vocal cords
Condensation of the expired gases on ETT
End-tidal capnography
Colorimetric detection of carbon dioxide
Observing for bilateral symmetric chest rise
Auscultation for equal breath sounds
Absence of stomach “gurgling”

Confirmation of Tube Placement

It is vitally important to confirm proper tube positioning after endotracheal intubation. Correct ETT placement may be confirmed by several methods, as illustrated in Table 149.3. The most confirmatory test is direct visualization of the ETT passing through the vocal cords. Fogging of the ETT is another sign of tracheal intubation, however, it has been reported to occur with esophageal intubations as well. Capnography and colorimetric detection of carbon dioxide are other commonly used methods for confirmation of endotracheal intubation.[28,29] Colorimetric endtidal carbon dioxide contains a pH-sensitive paper filter that turns from purple to yellow in the presence of carbon dioxide. Capnography can be erroneously positive with gastric intubation, if the patient has been improperly bag valve mask ventilated, causing significant gastric insufflation. Observing the patient for symmetric chest rise, auscultating for equal bilateral breath sounds over the lungs and the absence of a stomach gurgling sound made by air entering the stomach, also verifies tracheal intubation.

Alternative Airway Techniques

It may be difficult to obtain an artificial airway in certain clinical scenarios by conventional techniques. Examples include, cervical and oropharygeal trauma and difficult anatomy, such as excessive supraglottic redundant soft tissue. In order to prepare for such situations, it behooves the intensivist to become skilled in performing alternative techniques. The American Society of Anesthesiologists Task Force on Difficult Airway also incorporates alternative techniques in its recommended algorithm.[1] Various tools and equipment that facilitate alternative techniques include, fiberoptic, video, optical and mechanical methods for better viewing of the larynx, to expedite the passage of an ETT into the trachea. These devices are useful for the management of the difficult or

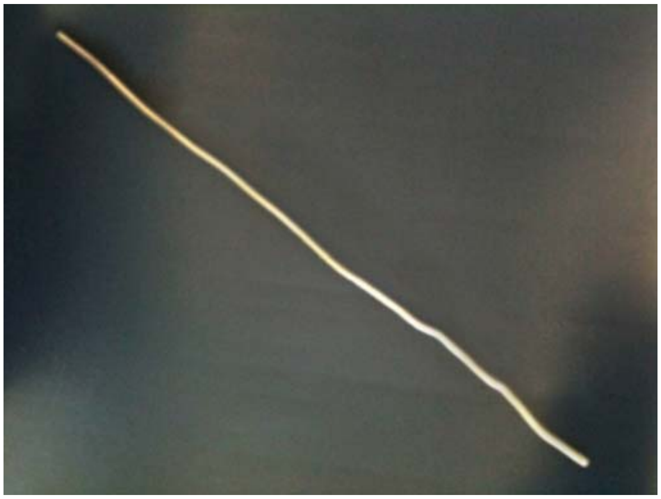

Fig. 149.11: A stylet

failed airway as well as for routine intubations. This section will discuss the types of devices designed to facilitate management of difficult and failed airways.

Stylets

A stylet is a device that can be inserted into the lumen of an ETT, in order to assist with tracheal tube placement (Fig. 149.11). A standard malleable metal stylet lends greater stiffness and adjusts the curvature of the ETT. This allows the tip to be directed through a poorly visualized glottis. The stylet must not project beyond the end of the ETT, in order to avoid potential airway injury. A specialized stylet adapted with advanced optics can provide a better view of the glottis than is obtained with direct laryngoscopy.

Lighted Stylets

A lighted stylet is equipped with a small light bulb at the distal end. Transillumination across the upper airway confirms proper placement, as the brightness will be significantly dimmed or disappear with esophageal intubation. An advantage of lighted stylet intubation includes, less risk of pharyngeal trauma compared to blind attempts when the larynx is not visualized.[30] A potential disadvantage is the need for low ambient lighting that may not be feasible in the critical care setting. A contraindication to the use of a lighted stylet is known abnormal upper airway anatomy.[30]

Intubating Introducer—Gum Elastic Bougie

The intubating introducer consists of a 60 cm stylet with a 30° angle distal tip. The bend allows the operator to direct the tip anteriorly under the epiglottis and through the vocal cords. The introducer is placed blindly into the glottis and advanced approximately 20–24 cm to the level of the teeth. There are two ways to confirm correct placement in the trachea. One way is to feel the clicking sensation, when the stiff stylet tip runs against the tracheal rings. The other sign of airway versus esophageal intubation is sensing resistance to further insertion.[31] The ETT is placed over the proximal end of the catheter and advanced into the glottis. Proper use of the introducer requires practice before introducers can be used successfully.[32] Mechanical trauma to airway structures from intubating stylets are rare.[33]

Fiberoptic Laryngoscope

Rigid fiberoptic laryngoscopes include the Bullard laryngoscope™ (ACMI Circon, Santa Barbara, CA) and the WuScope™ (Achi Corporation, San Jose, CA). Visualization of the larynx is performed, while the patient is in the neutral position, the preferred method, where cervical spine immobility is imperative in the trauma setting.[34,35] An advantage of this device includes, its easy portability. Unfortunately, unfamiliarity and cost of these devices limit their use.

Extraglottic Devices

Extraglottic airway devices for supralaryngeal ventilation can be further divided into cuffed, orally inserted hypopharyngeal airways and cuffed, orally inserted esophageal airways (Combitube ™).

Laryngeal Mask Airway (LMA)

The LMA is a supraglottic device, which consists of a silicone mask designed to fit over the pharynx and allow for gentle ventilation (Fig. 149.12). The advantages of the LMA include rapid, easy insertion, which can be mastered quickly. The entire construct is latex free and available in pediatric and adult sizes. In the setting of a difficult airway, it can be used for awake intubations, blind intubations or intubations combined with fiberoptic bronchoscopy. In addition, the LMA can be used as a conduit to endotracheal intubation.

Before the LMA is used, it should be inspected and tested for leaks. The patient should be positioned in the classic sniffing position and the lubricated LMA cuff is placed facing the patients tongue and advanced posteriorly along the palatopharyngeal curve from oropharynx to hypopharynx. Once resistance is met, the LMA should be pressed along the upper esophageal sphincter. The cuff is inflated with air to approximately

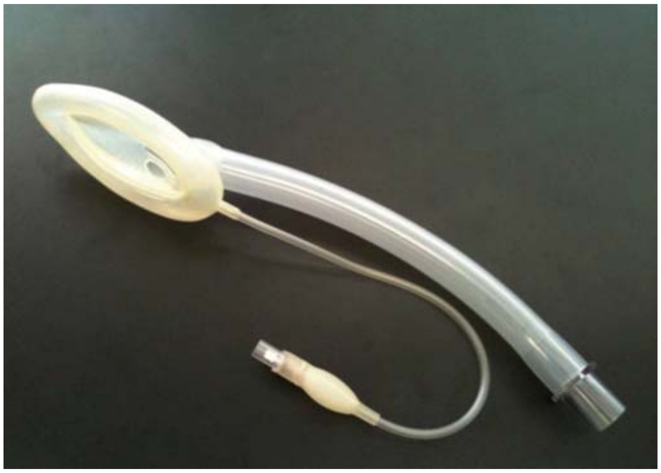

Fig. 149.12: Laryngeal mask airway

60 cm H_2O. The cuff of the LMA lies against the posterior pharyngeal wall and forms a seal. Positive pressure ventilation can be administered through the LMA provided the peak airway pressures do not exceed 20 cm H_2O.

This low-pressure cuff increases the risk of aspiration, if vomiting occurs during ventilation. Contraindications to placement include patients with limited mouth opening, pathologies, such as tumor, abscess, epiglottitis or bleeding at or above the vocal cords and in patients at risk for aspiration. Complications include a higher frequency of gastric sufflation, due to the lower sealing pressure of the cuff in comparison to endotracheal intubation.[36] Coughing and laryngospasm may occur, if the LMA makes contact with the vocal cords. The ProSeal™ LMA has a modified cuff, to provide a more effective seal than the standard LMA. It also comes with a drainage tube for gastric tube placement[36] and therefore, may be safer for use in patients at risk for aspiration. The LMA-Fastrach™ or intubating LMA is a modified standard LMA with a large bore metal tube, a metal handle and an epiglottis elevating bar for endotracheal tube insertion. A high success rate for intubation has been demonstrated with blind and fiberoptic insertion, using the intubating LMA.[37]

Esophageal-Tracheal Combitube™

The Combitube™ is a double lumen tube system with proximal (oropharyngeal) and distal cuffs that can be inserted blindly (Fig. 149.13). The design of the tube allows for ventilation through the distal tube, if properly inserted into the trachea. More commonly however, the distal tube is inserted into the esophagus, in which case, both the proximal (oropharyngeal balloon) and distal cuffs are inflated. The tube is properly placed in the esophagus, if there is no evidence of carbon dioxide detected with ventilation.

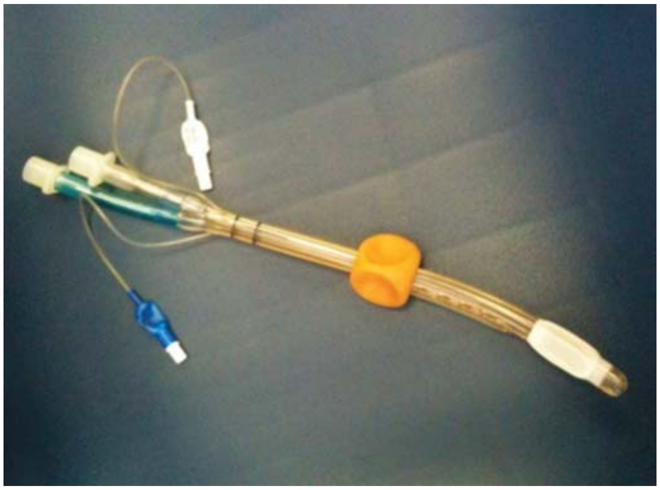

Fig. 149.13: A esophageal-tracheal tube

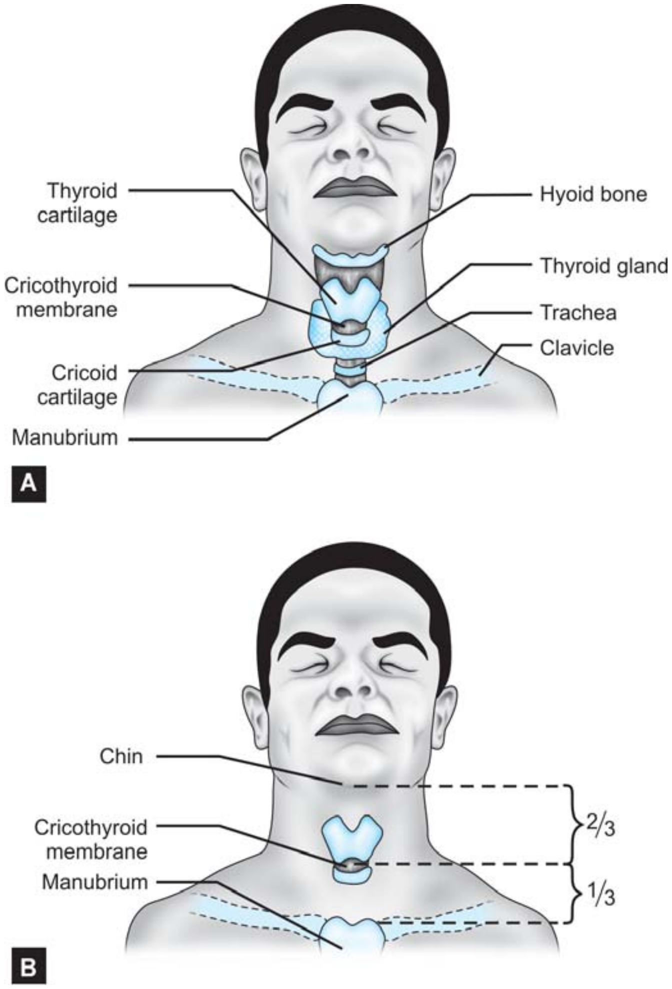
The ventilator is attached to the shorter tube for ventilation into the trachea. If the trachea is intubated, the longer tube is ventilated, which is similar to a conventional endotracheal tube. Drawbacks of the Combitube™ include inability to suction, when the distal tube is placed in the esophagus. The major contraindications of using the Combitube™ are esophageal pathologies, an intact gag reflex and in cases of caustic substance ingestion.[38] Complications of esophageal tracheal Combitube™ include esophageal injury, subcutaneous emphysema and pneumomediastinum.[39,40]

Fiberoptic Bronchoscopy

The use of a bronchoscope can be instrumental in the placement of an ETT in the mouth or the nose.[34] The ETT is placed over the bronchoscope, the scope passed through the glottis for direct visualization of the vocal cords and advanced beyond the vocal cords into the trachea. The ETT is advanced over the bronchoscope into the trachea. Flexible bronchoscopy is a helpful tool for difficult airway intubations in the hands of an experienced practitioner. It is particularly useful when upper airway anatomy has been distorted by tumors, trauma or congenital anomalies. It also allows for awake intubations with topical anesthesia and is particularly useful in patients with cervical injuries, where immobilization is crucial.[41] The bronchoscope may identify causes of acute hypoxia and help to remove secretions or blood in the airway. Limitations include operator inexperience and the need for patient cooperation.

Transtracheal Jet Ventilation

Transtracheal jet ventilation is performed by the placement of a large bore catheter (14-gauge) through the cricothyroid membrane (Figs 149.14A and B) into the trachea (needle cricothyroidotomy). The placement of the catheter is confirmed by aspiration of air before connecting to the ventilation system. High-pressure oxygen can be connected from the wall outlet via a Luer-lock connector. Complications with this technique include aspiration, bleeding and barotraumas, including pneumothorax, pneumomediastinum, subcutaneous emphysema and inadequate ventilation.



Figs 149.14A and B: A. Anatomy of the neck, B. Location of the cricothyroid membrane

Judith E Tintinalli, (Co-Editors), Gabor D Kelen, J Stephan Stapczynski, (Eds). Emergency Medicine: A Comprehensive Study Guide. McGraw-Hill, Medical Publishing Division 2004

Retrograde Intubation

Retrograde intubation involves the placement of a guide wire through a puncture in the cricothyroid membrane into the pharynx in a retrograde fashion. The guide wire is used to aid the placement of an endotracheal tube. An 18-gauge or larger needle attached to a 20 ml syringe partially filled with saline is advanced midline through the cricothyroid membrane. A large volume of air in the syringe will be seen when the trachea is entered. The needle is aimed superiorly and the syringe is removed. A guidewire is threaded through the needle into the oropharynx. The wire tip is retrieved with Magill forceps under direct visualization. An endotracheal tube is advanced down the trachea over the guidewire and the guidewire removed from the oropharynx. Contraindications to retrograde intubation include complete upper airway obstruction, laryngeal trauma, inability to open the mouth to retrieve the wire and urgent intubation, since retrograde intubation may take sometime.[42]

Surgical Airway

A surgical airway is indicated when other means of establishing an airway fail, such as cases of laryngeal trauma and facial injuries or in cases of long-term need of ventilatory support.

Cricothyroidotomy

Cricothyroidotomy (also called cricothyrotomy) establishes an airway, by making an incision in the cricothyroid membrane. Placement of the tracheostomy tube or modified ETT, through the opening establishes an airway for oxygenation and ventilation. This is the preferred method of a surgical airway in situations with supraglottic obstruction and can be lifesaving.

Needle cricothyroidotomy is performed by inserting a 12 or 14-gauge needle catheter through the cricothyroid membrane. The placement of the catheter is confirmed by aspiration of air, once in the tracheal lumen. The needle is withdrawn and the catheter connected to an oxygen supply. This procedure provides a temporary airway to oxygenate a patient in severe respiratory distress, when less invasive techniques (bag-valve-mask ventilation, LMA and ETT insertion) have failed.

A surgical cricothyroidotomy is performed by making a 1 cm transverse incision over the caudal part of the cricothyroid membrane.[43] Once the incision is made, a dilator is inserted to enlarge the incision. A scalpel handle may also be used to dilate the opening, by turning it 90°

to open the airway. Subsequently, an appropriately sized cuffed ETT or tracheostomy tube is inserted, secured with sutures and tied around the neck.

A cricothyroidotomy is absolutely contraindicated, when the patient can be safely orally or nasally intubated. Complications to this technique include bleeding, infection, vocal cord damage, posterior tracheal or esophageal rupture and tracheal stenosis.[44, 45]

Tracheostomy (Percutaneous vs Surgical)

Tracheostomy is a commonly performed procedure for prolonged mechanical ventilation.[46] The timing of tracheostomy should be individualized and based on the likelihood of benefit and predicted need for prolonged ventilation.[47] Early tracheostomy has been advocated in the literature to improve survival and decrease ventilator days.[48] However, recent findings may suggest otherwise.[49] Tracheostomy may be performed by an open surgical approach or by percutaneous dilatation technique.[50,51]

Percutaneous tracheostomy is a common procedure performed at the bedside or in the operating room. Successful performance of the bedside percutaneous procedure is related to the expertise of the operator and ancillary personnel. Percutaneous tracheostomy requires less time to perform and is less expensive than a surgical approach.[52,53] The first or second tracheal interspace is the preferred site for tracheostomy tube placement. The neck is extended to open the tracheal cartilage interspaces and the surgical field prepped and draped with aseptic technique. Local anesthesia is injected subcutaneously at the incision site and a 2 cm skin incision is made over the first or second tracheal interspaces. Hemostats or curved forceps are used to bluntly dissect down to the anterior tracheal wall. A bronchoscope is inserted through the existing ETT and kept just proximal to the end of the tube. The ETT cuff is deflated and the tube retracted to the point above the first tracheal ring for bronchoscopic visualization. The ETT cuff is reinflated and scope position is maintained for bronchoscopic visualization of tracheostomy insertion.

An introducer needle attached to a saline-filled syringe (bevel facing down) is inserted midline through the skin incision and bronchoscopically visualized. The trachea is punctured, confirmed by bubbling in the saline, while visualized by bronchoscopy. The syringe is disconnected and a J-tipped guidewire is advanced through the needle into the trachea and down to the carina. The needle is then removed over the guidewire. Sequentially larger dilators are advanced over the wire, in order to dilate the stoma. Once the incision is dilated, a tracheostomy tube is placed with Seldinger technique and the wire and obturator removed. The bronchoscope is removed from the ETT and inserted into the tracheostomy tube to validate proper placement. After confirmation of correct tracheostomy tube placement, the ETT is removed and the tracheostomy tube is secured.

Disadvantages of percutaneous tracheostomy compared to surgical tracheostomy include an increased risk of anterior tracheal injury and posterior tracheal wall perforation. Contraindications may include uncorrectable bleeding diathesis, gross distortion of the neck from masses (hematoma, tumor and thyromegaly), scarring from previous neck surgery, infection in the soft tissues of the neck and inability to extend the neck. Complications include stoma infections, bleeding, accidental extubation, pneumothorax, tracheal ring fracture and tracheal stenosis, these complications are listed in Table 149.4.[6,54,55]

TABLE 149.4: Complications of tracheostomies
Stoma infection
Bleeding
Tube displacement/extubation
Barotrauma—subcutaneous emphysema, pneumomediastinum, pneumothorax
Recurrent laryngeal nerve injury
Tracheoesophageal fistula
Tracheocutaneous fistula
Tracheal ring fracture
Tracheal stenosis

Surgical tracheostomy is usually performed in the operating room by surgeons under general anesthesia. A 2 cm transverse incision is made 2 cm above the suprasternal notch.[56] Midline dissection of the cervical fascia and underlying neck muscles exposes the thyroid gland. [57] A vertical tracheostomy is created between the second and fourth tracheal ring and the incision is dilated. A tracheostomy tube is placed through the dilated stoma, secured into place and the ETT is removed.[58]

CONCLUSION

Acquiring expert knowledge in securing the airway is a critical step, when caring for patients in the intensive care unit. Understanding the advantages and potential pitfalls for various intubation and airway techniques is essential. A multidisciplinary team approach further improves outcome, given the heterogeneous patient populations that exist in the intensive care setting.

Analgesia and Sedation in the ICU

Karan Madan, Ritesh Agarwal

INTRODUCTION

Critically ill patients experience a wide variety of stresses in the Intensive Care Unit (ICU) environment. The causes of patient discomfort may be obvious like trauma and invasive procedures or related to prolonged immobility, nursing care and various forms of monitoring and therapy.[1] Pain, presence of catheters or tubes and disruption of sleep are important sources of distress to the patients in the unfamiliar ICU enclosure. Approximately one-third of the ICU patients are mechanically ventilated.[2] These patients usually experience the greatest levels of stress and discomfort in the harsh ICU environment.

Provision of effective and safe care coupled with prevention of patient distress constitutes one of the most important principles in caring for the critically ill. Non-pharmacologic strategies can be tried at optimizing patient comfort but many of critically ill patients, especially those receiving mechanical ventilation, require administration—of analgesic and sedative medications for management at some or the other time during their stay in the ICU. Also, a number of patients in the ICU develop delirium which may be associated with increased long-term mortality and poor psychological outcomes, like post-traumatic stress disorder.[3]

The management of pain, agitation and delirium are extremely critical issues in ICU patient management. Appropriate analgesia and sedative use practice is a neglected field in most ICU’s. Optimal practices are associated with better patient outcomes.

TEAMWORK (MULTIDISCIPLINARY MANAGEMENT) AND PATIENT FOCUSSED CARE

ICU sedation and analgesia practice is one of the prime areas of critical care in which teamwork plays a pivotal role. This involves a continuous interaction between the treating physician, the nursing staff, pharmacists and other members involved in patient care.[4] The clinical pharmacist can inform the treating team regarding the effects of potential drug interactions and the choice of the medication, depending upon the individual patient characteristics.

Every patient requires comprehensive focussed care for optimal outcomes. Based upon the underlying illness and current patient state, decisions need to be taken and frequently reassessed. The choice of medication and the target level of sedation and analgesia need to be individualized. The core principle of patient focussed care is based on the varying need of sedative and analgesic medications in different patients at different times.[5] Higher levels of sedation and even neuromuscular blockade are required when using non-conventional techniques, such as high frequency oscillatory ventilation or positioning the Acute Respiratory Distress Syndrome (ARDS) patient prone.[6,7]

A comprehensive interdisciplinary plan needs to be formulated to provide ideal levels of comfort and also to prevent oversedation. In the resource limited settings and in places with a lack of manpower, the role of the treating physician assumes the prime importance in taking therapeutic decisions, based on individual patient characteristics and guiding the other members of the team in ensuring compliance. Nursing staff play an extremely important role as they interact with the patients most frequently.

INITIAL EVALUATION AND MEDICATION RECONCILIATION

It is extremely important at the time of initial evaluation to carefully assess various factors which contribute to patient discomfort and distress. Underlying medical illness, mechanical ventilation, invasive monitoring, hospital acquired illnesses, various medications and acute medical or surgical illnesses, all contribute to pain, anxiety and delirium in the ICU patients. Initial interventions should be targeted at appropriate management of the predisposing conditions along with sedative, analgesic and antipsychotic medications as deemed appropriate, according to the clinical situation.

Medication reconciliation is the comprehensive evaluation of a patient's medication regimen anytime there is a change in therapy, in an effort to avoid medication errors such as omissions, duplications, dosing errors or drug interactions, as well as to observe compliance and adherence patterns. The concept of medication reconciliation is extremely important when patients move into and out of the ICU. As many as 50% of all medication errors occur at the time of ICU admission or discharge. In approximately 60% of the patients, regular medications are discontinued at the time of admission to the ICU.[8-10]

In the context of sedation and analgesia, omission of medications like antidepressants, anxiolytics, analgesics or antipsychotics can lead to many undesirable consequences.[5] There are also risks of precipitation of withdrawal symptoms.

CONSEQUENCES OF OFF-TARGET SEDATION AND ANALGESIA

Improper assessment and inadequate treatment of pain and agitation in the ICU is associated with a number of adverse consequences (Table 150.1). It is exceedingly important to properly assess pain and agitation in the ICU and provide an adequate level of analgesia and sedation to improve patient outcomes.

TABLE 150.1: Consequences of off-target sedation and analgesia

A. *Consequences of inadequate pain relief and agitation*
  - Self-extubation and removal of other tubes and catheter devices
  - Violent behavior
  - Patient ventilator dys-synchrony
  - Excessive pain leading to increased agitation and anxiety
  - Precipitation of myocardial ischemia in susceptible patients
  - Pain related immunosuppression

B. *Consequences of oversedation*
  - Neural compression leading to pressure nerve palsies
  - Precipitation of delirium
  - Prolonged duration of mechanical ventilation
  - Prolongation of ICU and hospital length of stay (LOS)
  - Breach in skin integrity leading to pressure sores and infections
  - Increased incidence of problems associated with prolongation of mechanical ventilation, e.g. VAP (Ventilator associated pneumonia)

NEED FOR FREQUENT PATIENT ASSESSMENT

A large proportion of ICU patients are oversedated as observed in epidemiological surveys.[11,12] An important finding was the demonstration that during night time, an extremely low proportion of nursing staff perceived their patients to be oversedated. The sleepy state during night time was accepted as the expected state at those hours, thereby contributing to oversedation.[12]

This deliberates a need for more frequent assessment of pain and agitation in the ICU.

ASSESSMENT OF PAIN, SEDATION AND AGITATION IN THE ICU

Assessment of pain, level of consciousness, agitation and cognition are central to patient management. Decisions regarding change in medication can be done accordingly.

USE OF VALIDATED SCALES AND TOOLS

The use of validated assessment methods like sedation scales, pain and delirium assessment tools provides homogeneity of assessment between different caregivers, enhances communication and provides objective measurement and is therefore cardinal to patient focussed care. In addition, the use of scales permits medication titration to desired levels thereby minimizing the risk of oversedation and provision of adequate analgesia.

The use of sedation scales has been associated with a decrease in the duration of oversedation, decreased sedation costs, reduced inotrope use, decreased sedative and analgesic medication use, a decrease in the incidence of nosocomial infections and a reduction in the duration of mechanical ventilation.[13-15]

The society of critical care medicine (SCCM) clinical practice guidelines[1] recommend establishing and regularly redefining a sedation goal for each patient. It is also recommended that a regular assessment should be performed and response to therapy documented.

Assessment of Pain

Experiencing pain is an extremely distressing experience for any individual. The issue of pain control in critically ill patients assumes an even greater magnitude and nearly 90% of the patients have unpleasant memories of their ICU experience, including pain.[16] It should never be forgotten that all critically ill patients have the right to adequate analgesia.[1] Relatively simple procedures that occur frequently in the ICU, such as suctioning and repositioning are usually reported as the greatest source of discomfort to the ICU patients.[17]

Pain Assessment Methods

Communicative Patients

The gold standard for assessment of pain is the patient self report. Patients can be assisted to communicate the pain that they are experiencing, and an attempt should be made to quantify the intensity of pain experienced.

Numeric rating scale (NRS)/Numeric pain scale (NPS): The Numeric rating scale (NRS) or Numeric pain scale (NPS) is recommended by the SCCM to assess pain.[1] It utilizes rating of pain on a 0 to 10 scale with 0 indicating no pain and 10 being the worst pain experienced. It has been successfully used for pain evaluation in critically ill patients who are able to communicate.[17]

A body outline diagram along with the NPS can help in localization of the site of pain. Patients unable to point (including some but not all ventilated patients) can communicate experiencing pain by blinking or squeezing their eyes.[18] In addition, the intensity of pain can be quantified when the observer points to a number on the NPS and the patient nods or blanks in response. Patient cultural and language differences must be kept in mind when assessing pain according to patient self report.[19] Utilization of communication accordingly may be more appropriate.

Non-communicative Patients

Physiologic indicators like hypertension, tachycardia and tachypnea are usually thought to signify the presence of pain but their use has fallen out of favor off late, due to their lack of specificity.[20] A number of scales have been developed, which rely on the patients behavioral and physiologic parameters to signify the presence of pain in the non-communicative adults. Critically ill adults share certain similarities to the pediatric population. They may not be able to communicate the presence of pain like a small child.[21]

The COMFORT scale[22] and the FLACC (Face, Legs, Activity, Cry, Consolability Observational Tool) scale[23] were developed for use in the pediatric population and are not extensively validated for use in the adults. The PAIN (pain assessment, intervention, and notation) algorithm incorporates observation of pain related physiological and behavioral variables but in its original form is too cumbersome for routine ICU use.[24] The Behavioral pain scale (BPS) and the Critical-Care Pain Observation Tool (CPOT) are objective pain assessment scales which can be used in ICU patients during mechanical ventilation. Both have been tested for validity and reliability.

Behavioral Pain Scale (BPS)

Behavioral pain scale[25] is based upon three variables: Facial expression, upper limb movements and compliance with mechanical ventilation (Table 150.2). These variables are thought to signify the presence of pain. Each of these variables can have a value from 1 to 4. The score can range from 3 to 12, which is obtained by adding up the value for each variable. Score of 3 indicates no pain related behavioral response, whereas a score of 12 indicates the maximal pain related behavioral response.

TABLE 150.2: Behavioral pain scale

Item	*Description*	*Score*
Facial expression	Relaxed	1
	Partially tightened (e.g. brow lowering)	2
	Fully tightened (e.g. eyelid closing)	3
	Grimacing	4
Upper limbs	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with ventilation	Tolerating movement	1
	Coughing but tolerating ventilation for most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

Scores from three domains added up. Total score ranges from 3 to 12.[25]

TABLE 150.3: Critical care pain observational tool[27]

Indicator	*Description*	*Score*
Facial expression	No muscular tension observed Presence of frowning, brow lowering, orbit tightening and levator contraction All of the above facial movements plus eyelid tightly closed	Relaxed, neutral: 0 Tense: 1 Grimacing: 2
Body movements	Does not move at all (does not necessarily mean absence of pain) Slow, cautious movements, touching or rubbing the pain site, seeking attention through movements Pulling tube, attempting to sit up, moving limbs/thrashing, not following commands, striking at staff, trying to climb out of bed	Absence of movements: 0 Protection: 1 Restlessness: 2
Muscle tension	No resistance to passive movements Resistance to passive movements Strong resistance to passive movements, inability to complete them	Relaxed: 0 Tense, rigid: 1 Very tense or rigid: 2
Compliance with the ventilator	Alarms not activated, easy ventilation Alarms stop spontaneously Asynchrony: blocking ventilation, alarms frequently activated	Tolerating ventilator or movement: 0 Coughing but tolerating:1 Fighting ventilator: 2
OR		
Vocalization (Extubated patients)	Talking in normal tone or no sound Sighing, moaning Crying out, sobbing	Talking in normal tone or no sound: 0 Sighing, moaning: 1 Crying out, sobbing: 2
Scores for each of the four domains are added up. Total score of 0 to 8.		

BPS is a scale with demonstrated discriminant validity for the presence of pain.[25] It also possesses fair interobserver reliability.[26] With deepening levels of sedation, patient responsiveness on BPS decreases.[25]

Critical Care Pain Observational Tool (CPOT)

Four behavioral domains are assessed in the CPOT: Facial expression, body movements, muscle tension and compliance with ventilation (Vocalization for extubated patients) (Table 150.3). Each variable can have a score from 0 to 2. The score of individual variables is added-up to obtain the total score which can range from 0 (No pain) to 8 (Maximal pain).

Like the BPS, CPOT has discriminant validity for the presence of pain, also possesses fair inter rater reliability.[27] CPOT was demonstrated to show similar scores with response to painful stimuli in both conscious and unconscious state.[27] However, this might not be true at levels of deep sedation.

Although both BPS and CPOT are seemingly similar, they have certain important differences. CPOT might possess certain advantages over BPS. As only upper limb movements are assessed by the BPS, there is a potential for inaccurate assessment if external equipment hampers the patient's upper limb movements. The ventilation assessment parameters of BPS are not measurable and might contribute to inter rater differences in assessment. CPOT has well defined descriptors of measurement. In addition, CPOT appears to be more logical as a score of 0 in CPOT indicates no pain as compared to a score of 3 in BPS.[19]

Neither of these two instruments have been evaluated for the ability to differentiate responses to pain prior to and after receiving analgesics. However, both BPS and CPOT are reliable and valid instruments for the assessment of pain in the ICU and their use is recommended.

Other Methods for Assessment of Pain[19]

Pain risk profile: It is based on the identification of various individual and environmental factors which may contribute to pain in ICU patients. Early identification of susceptible individuals may allow early initiation of appropriate analgesic therapy.

Surrogate Reporting

This method relies on the information provided by the surrogates, usually family members. An important component of this method is the proper education of the surrogate. The clinician should instruct the family member to consider the actual experiences that the patient might be going through. The surrogate based on the previous experiences of the patient's response to pain of a similar degree can provide valuable information. Although the evidence regarding surrogate assessment of pain remains equivocal, this method may be useful in situations where the patient is unable to self report.

Analgesic Response

This is based on the principle of therapeutic challenge with analgesics. It can be tried when the patient is unable to self report and there is likelihood of presence of pain. In case of no response, alternative causes for the patient's state should be sought.

Assessment of Sedation and Agitation in the ICU

The level of sedation in the ICU is usually assessed using a sedation scale. In one of the earliest works in this regard, it was demonstrated that use of a sedation scale is associated with improved quality of sedation and a statistically significant reduction in the hours of oversedation.[13] An ideal sedation scale should have several important characteristics for an adequate assessment[28] (Table 150.4).

The SCCM guidelines recommend the use of a validated sedation assessment scale. It also recommends that sedation of agitated critically ill patients in the ICU should be started only after providing adequate analgesia and treating reversible physiological causes. Administration of sedatives when the patient's distress is actually due to pain may result in increased agitation.

TABLE 150.4: Characteristics of an ideal sedation scale

- Rigorous multidisciplinary development
- Simple recording and computing of data
- Accurate description of sedation and agitation within well defined categories
- Guides drug titration and thereby management of therapy
- Validity and inter rater reliability in ICU patients
- Ease of administration, recall and interpretation

TABLE 150.5: Various sedation scales

- Ramsay Sedation Scale (RSS)[29]
- Richmond Agitation-Sedation Scale (RASS)[30]
- Sedation Agitation Scale (SAS)[31]
- Motor Activity Assessment Scale (MAAS)[32]
- Adaptation to the Intensive Care Environment (ATICE) instrument[33,34]
- Minnesota Sedation Assessment Tool (MSAT)[34]
- Vancouver interaction and calmness scale (VICS)[35]

A number of scales have been developed (Table 150.5). Some of them have been extensively validated and tested for inter rater reliability in heterogeneous patient populations.

The earliest sedation scale, described nearly 35 years ago was the Ramsay sedation scale.[29] Since then, a number of sedation scales have been developed for clinical and research use which in addition to the levels of sedation, permit the simultaneous evaluation of other parameters like agitation, cognition and patient ventilator dys-synchrony.

These scales have certain differences in structure but share common themes of assessment. They assess the levels of patient sedation based on a common principle of observing response to increasing levels of stimulation. An initial observation is made to see whether the patient is awake. If not, the response to auditory and subsequently more intensive (physical) stimulation is noted. The responses indicate a progressively deepening level of sedation. In addition to sedation, simultaneous assessment of the following parameters can be done:

Cognition

- Cognition refers to the ability to follow commands.
- RASS and ATICE include the simultaneous assessment of cognition.
- RASS additionally permits the assessment of sustainability.

Agitation

Agitation is assessed by many scales. It is measured as a separate subscale in ATICE and VICS. Agitation assessment is incorporated into a single scale in SAS, MAAS and RASS.

RASS is one of the most frequently used sedation scales (Table 150.7). It is performed using a series of steps: Observation of behaviors (score +4 to 0), followed (if necessary) by assessment of response to voice (score -1 to -3), followed (if necessary) by assessment of response

TABLE 150.6: Ramsay sedation scale (RSS)

Sedation level	*Definition*
1	Patient anxious and agitated or restless or both
2	Patient cooperative, orientated, and tranquil
3	Patient responds to commands only
4	Brisk response to a light glabellar tap or loud auditory stimulus
5	Sluggish response to a light glabellar tap or loud auditory stimulus
6	No response to a light glabellar tap or loud auditory stimulus

Awake levels 1 to 3, Asleep levels 4 to 6.[29]

to physical stimulation, such as shaking shoulder and then rubbing sternum if no response to shaking shoulder (score -4 to -5).

With RASS, sedation levels are assigned negative numeric values, whereas agitation levels are denoted by positive numbers thereby enabling sedation and agitation differentiation in a single scale. By using a sedation scale, a target level of sedation can be established and accordingly medication titration can be done. In addition, oversedation can be detected and de-escalation of drugs can be done accordingly.

Light sedation levels - RSS (2-4), RASS (-2 to +1).

Deep sedation levels - RSS (4–6), RASS (-4 or -5), SAS (1 to 2).

RSS, RASS and SAS are the most extensively used and validated scales. However, RSS does not grade agitation.

Objective Measurement of the Cerebral Activity in the ICU

Objective measurement of the brain activity can be done using the cerebral function monitors. These monitors record the EEG signals from the cerebral cortex, process them through various algorithms, in order to yield a dimensionless numeric value which ranges from 0 (complete EEG suppression) to 100 (awake).[21]

The various available systems are the Bispectral index (BIS),[36] Patient State Index (PSI),[37] narcotrend index[38] and the Cerebral State Index (CSI).[39] Their utility in the ICU setting is limited by certain factors, like the Electromyography (EMG) interference or electrical current-related artifact which can lead to erroneous BIS values. Routine use of these tools is not recommended by the SCCM.[1]

Additional approaches for objective monitoring of brain function in the ICU include response entropy and state entropy[40] and auditory-evoked potentials.[41] In certain situations, the use of BIS may be useful like in assessment of consciousness in patients who are paralyzed with neuromuscular blocking agents and patients who are under the influence of deep sedation.[1]

MANAGEMENT OF ANALGESIA AND SEDATION IN THE ICU

Most patients in the ICU require the administration of sedative-analgesic medications for optimizing comfort. The most important group comprises the mechanically ventilated patients, many of whom face the extremes of physiologic stress. In them, sedatives and analgesics are

TABLE 150.7 : Richmond agitation-sedation scale (RASS)[30]

Score	*Term*	*Description*
+4	Combative	Overtly combative or violent, immediate danger to staff
+3	Very agitated	Pulls on or removes tube(s) or catheter(s) or exhibits aggressive behavior toward staff
+2	Agitated	Frequent non-purposeful movement or patient-ventilator dys-synchrony
+1	Restless	Anxious or apprehensive but movements not aggressive or vigorous
0	Alert and calm	
–1	Drowsy	Not fully alert, but has sustained (>10 seconds) awakening, with eye contact, to voice
–2	Light sedation	Briefly (<10 seconds) awakens with eye contact to voice
–3	Moderate sedation	Any movement (but no eye contact) to voice
–4	Deep sedation	No response to voice, but any movement to physical stimulation
–5	Unarousable	No response to voice or physical stimulation

TABLE 150.8: Dosing of the selected sedative analgesic medications

Drug	*Loading dose*	*Maintenance dose*
Morphine	2-4 mg IV bolus	0.07-0.5 mg/kg/h
Fentanyl	25-50 mcg IV bolus	0.7-10 mcg/kg/h
Hydromorphone	0.2-0.6 mg IV bolus	7-15 mcg/kg/h
Midazolam	2-5 mg IV bolus	0.04-0.2 mg/kg/h
Lorazepam	2-4 mg IV bolus	0.01-0.1 mg/kg/h
Diazepam	0.03-0.1 mg/kg	-
Propofol	-	5-80 mcg/kg/min
Dexmedetomidine	0.5-1 mcg/kg over 10 min	0.2-0.7 mcg/kg/hr
Remifentanil	1 mcg/kg over 1 min	0.6-15 mcg/kg/hr

required to improve patient ventilator synchrony and oxygenation.[42]

Intravenous route is the preferred route of administration, as it allows better dose titration, has a faster onset of action and higher bioavailability than other routes (Table 150.8). Intermittent therapy should be used wherever possible and continuous infusions should be avoided since continuous IV sedation is associated with prolonged duration of mechanical ventilation and increased Length of Stay (LOS) in the ICU.[43]

Analgesic Medications

It is recommended by the SCCM to establish a therapeutic plan and goal of analgesia for each patient which should be communicated to all caregivers to ensure consistent analgesic therapy.[1] Pharmacotherapy with opioid analgesic agents is the mainstay of provision of analgesia to patients in the ICU. Acetaminophen and the nonsteroidal anti-inflammatory agents (NSAIDs) possess weak analgesic activity and may lead to adverse effects in patients who are critically ill. Acetaminophen has a limited role in critically ill patients in provision of relief from mild to moderate pain or discomfort and use as an antipyretic agent.[1]

Opioid Analgesics

Mechanism of action of opioids: Opioids act through stimulation of opioid receptors. The opioid receptors are the μ, κ, and δ opioid receptors, which are widely distributed throughout the peripheral tissues and the central nervous system.[44] The μ receptor is the main opioid receptor, subdivided into the μ1 and the μ2 subtypes. μ1 receptors are responsible for the mediation of analgesia, whereas μ2 receptor binding leads to constipation, nausea and respiratory depression. κ receptor binding mediates spinal analgesia, pupillary constriction and the sedative effects of opioids.

It is important to note that although opioid administration may lead to mild to moderate anxiolytic effect, they do not produce amnesia. Opioids have an excellent cough suppressant action. In addition, they provide a marked relief in the subjective sense of dyspnea. By a combination of these two effects, they may be particularly helpful in mechanically ventilated patients.[45]

Morphine, Fentanyl and Hydromorphone are the most commonly used opioid analgesic agents in the ICU. *Morphine:* Morphine is a μ receptor agonist, possesses weak κ and δ receptor agonistic activity. It has poor lipid solubility, therefore has a relatively slow onset of action (5 to 10 minutes). It is primarily metabolized by glucuronidation in the liver, which leads to the generation of morphine 6 glucuronide and 3 glucuronide. Morphine 6 glucuronide has an activity of nearly 20 times that of morphine.[46] The excretion of both morphine and the active metabolites occur through the kidney. Morphine should therefore be avoided in patients with renal insufficiency, as it can accumulate and lead to prolonged drug effects.

Fentanyl: Fentanyl is a μ receptor agonist which has high lipid solubility, therefore has a rapid onset of action (< 1 min). Fentanyl is metabolized to inactive metabolites in the liver which undergo renal excretion. Fentanyl is preferred in patients with renal insufficiency. Cautious use should be done in patients with endstage renal disease, as fentanyl itself may accumulate at high doses. Owing to its high lipophilicity, repeated dosing or infusion can lead to a prolonged duration of effect, as the drug re-enters the plasma after discontinuation.[45] In acutely distressed patients, Fentanyl is the preferred agent for rapid onset of analgesia.

Hydromorphone: Hydromorphone is a μ receptor agonist with a duration of action and half-life nearly similar to morphine. However, its hepatic metabolism (by glucuronidation) leads to inactive metabolites (hydromorphone-3 glucuronide) making hydromorphone the opioid of choice in patients with endstage renal disease.[42]

Remifentanil

Remifentanil, an ultrashort acting selective μ receptor agonist is emerging as a promising opioid analgesic for use in the critically ill patients. The drug has unique pharmacokinetics in that it undergoes rapid metabolism by nonspecific blood and tissue esterases to an inactive metabolite, remifentanil acid. The drug is intensely lipophilic (onset of action < 1 min) and approximately 250 times more potent than morphine.[47] The terminal half life of the drug is approximately 10 to 20 minutes.

Because of the short duration of action, remifentanil may be preferable for analgesia in patients requiring frequent neurological assessments. Although the ultrashort action is beneficial in avoidance of prolonged drug effects, pain may rapidly emerge after drug discontinuation and longer acting agents may need to be administered to patients with ongoing pain.

Other agents: Meperidine with an onset of action and half-life similar to morphine should not be routinely used for analgesia in the ICU.[48] It has an active metabolite, normeperidine, a CNS stimulant which can cause neuroexcitation, manifested as tremors and seizures.[49]

Side Effects of Opioids

- *Respiratory depression:* Opioids lead to dose dependent, centrally mediated respiratory depression with respiratory rate decreased initially with preserved tidal volumes. As the dosage increases, tidal volume also is reduced and ventilatory response to hypoxia is obtunded.[45]
- *Hypotension:* Opioid induced hypotension is of particular concern in hypovolemic and hemodynamically unstable patients[50] and can occur in euvolemic patients also. By blunting the sympathetic tone, vagally mediated bradycardia, histamine release and increase in systemic venous capacitance, opioids can cause a precipitous fall in blood pressure.[51]
- *Gastric retention and ileus:* Routine use of stool softeners and stimulant laxatives may minimize opioid induced constipation but is often ineffective. Because of gastric hypomotility, small bowel intubation for feeding may be required.
- *Other side effects:* Muscle rigidity, urinary retention, nausea and pruritus.

Sedative Medications

Benzodiazepines

This class of drugs, which act by potentiating the Gamma-Aminobutyric Acid (GABA) receptor complex activity are the most commonly used sedative agents in intensive care. Benzodiazepines possess anxiolytic and anticonvulsant properties. They are potent inducers of anterograde amnesia but do not cause retrograde amnesia.[42] The pharmacologic effect depends on the degree of GABA receptor binding. Approximately 20% binding is associated with anxiolysis, 30–50% with sedation, and 60% with hypnosis.[52]

Benzodiazepines are associated with a dose dependent respiratory depression which is particularly marked when co-administration is done with opioids.[45] They can lead to hypotension particularly in hypovolemic patients. They can modulate the anticipatory pain response thereby can lead to reduction in the dose of opioids administered (opioid sparing effect).[53]

Midazolam

Midazolam is a rapidly acting, water soluble benzodiazepine (onset of action within 5 minutes) which has a short duration of action. It is oxidized by the cytochrome P450 (CYP 3A4) enzyme system in the liver leading to the production of water soluble hydroxylated metabolites. The primary metabolite is 1-hydroxymidazolam glucuronide, a CNS depressant which can cause prolonged sedation especially if kidney failure is present, as it is renally excreted. Obese patients and patients with hypoalbuminemia can also have prolonged sedation after midazolam administration.[54] CYP 3A4 inhibiting drugs like ketoconazole, itraconazole and erythromycin can lead to prolongation of sedative effects of midazolam.[42]

Because of unpredictable awakening and time to extubation when midazolam infusions continue longer than 48–72 hours, it is recommended for short-term use only. Midazolam is a preferred agent for rapid sedation of acutely agitated patients.

Lorazepam

Lorazepam has an onset of action within 5 to 20 minutes and the effect lasts for up to 6 to 8 hours. Unlike midazolam, hepatic metabolism of lorazepam leads to production of inactive metabolites which are excreted by the kidney.[45] An important concern with lorazepam administration is propylene glycol toxicity. Propylene glycol is used as a solubility enhancer of the drug for intravenous preparations. The toxicity may manifest as hyperosmolar states, worsening metabolic acidosis and acute tubular necrosis.[42] Monitoring of serum Osmolal gap should be done in patients receiving 50 mg per day and greater or > 1 mg/kg of lorazepam per day. An osmolal gap greater than 10 to 15 indicates significant accumulation of propylene glycol.[55] Treatment involves discontinuation of lorazepam infusion. In severe cases, hemodialysis provides effective removal of propylene glycol.[56]

Only a few randomized trials have compared midazolam with lorazepam for prolonged infusions. No significant difference in time to awakening was demonstrated in two studies. However, a double blind randomized controlled trial reported significant delays in emergence with lorazepam (31.1 hours for lorazepam vs 14.9 hours for midazolam for deep sedation after 72 hours infusion), as compared to midazolam.[57–59]

Lorazepam use in the ICU was found to be an independent risk factor for transition to delirium, even after adjusting for covariates.[60] Fenatanyl, propofol and morphine were also associated with higher odds ratio but not reaching statistical significance, in the same study.

Although lorazepam is recommended for the sedation of most patients via intermittent IV administration or continuous infusion,[1] in view of the possible concerns regarding prolonged emergence times, risk of propylene glycol toxicity and possible increased risk of delirium, prolonged infusions of lorazepam should be used cautiously. Midazolam is a better option in patients with normal renal and liver function parameters.

Propofol

Propofol (2,6 diisopropylphenol) is a widely used ICU sedative. Like the benzodiazepines, it possesses sedative and hypnotic properties and provides amnesia.[61] However, its site of binding on the GABA receptor is different from that of the benzodiazepines. It lacks analgesic properties therefore patients may require a greater dose of opioids for pain relief if receiving propofol rather than benzodiazepines.[62]

It is profoundly lipophilic, therefore crosses the blood-brain barrier, and rapid redistribution after infusion discontinuation leads to quick emergence times.[45] SCCM guidelines recommend propofol as the preferred sedative agent, when rapid awakening is important like in neurological assessment. Propofol reduces cerebral blood flow and metabolism and decreases the intracranial pressure.

Although propofol is metabolized in the liver by conjugation to metabolically inactive metabolites, clearance apparently is not significantly altered by hepatic or renal disease.[63] Clearance of the drug is slowed down in the elderly patients. Propofol causes profound respiratory depression, can also cause hypotension, especially in hypovolemic patients. Airway should be secured or intubation should be at standby whenever administering propofol.[45]

Propofol is a caloric source and provides 1.1 kcal/ml from fat.[42] Prolonged infusions may be associated with hypertriglyceridemia and also pancreatitis, therefore serum triglyceride levels should be monitored.[64] It is recommended to monitor triglyceride concentrations after two days of propofol infusion and also to include the total caloric intake from lipids in the nutrition support prescription.[1]

A number of randomized controlled trials have compared propofol with midazolam for sedation in the ICU. In a systematic review of 27 RCTs,[65] propofol use was associated with more effective sedation (longer duration of adequate sedation) and shorter weaning time for short-term infusions (<36 hours) but was associated higher adverse event (arterial hypotension and hypertriglyceridemia) rates. When daily interruption of sedation (DIS) was routinely used with both drugs, the duration of mechanical ventilation was similar.[66] In a trial comparing propofol infusion and DIS with intermittent lorazepam, duration of MV was significantly reduced with propofol and DIS.[67]

Propofol infusion syndrome (PRIS): Propofol infusion syndrome is a rare complication seen with infusion of propofol.[68] It is characterized by acute refractory bradycardia leading to asystole in the presence of one or more of the following: Metabolic acidosis (base deficit >10 mmol.l^{-1}), rhabdomyolysis, hyperlipidemia and enlarged or fatty liver. This potentially fatal condition is typically associated with propofol infusions at doses higher than 4 mg/$kg^{-1}.h^{-1}$ for greater than 48 hours duration. This is likely to occur from mitochondrial respiratory chain inhibition or impaired mitochondrial fatty acid metabolism mediated by propofol. Treatment involves immediate discontinuation of propofol and supportive treatment with hemodialysis or hemoperfusion, as the clinical setting dictates.

Dexmedetomidine

Dexmedetomidine is the dextro enantiomer of medetomidine which is the methylated derivative of etomidine. It is a highly specific alpha-2 receptor agonist with a specificity for the alpha-2 receptor seven times that of clonidine and an alpha-2/alpha-1 binding affinity ratio of 1620:1.[69] The drug possesses anxiolytic, sedative and analgesic properties. The mechanism of action is multipronged with sedation and anxiolysis via receptors within the locus ceruleus and analgesia via receptors in the spinal cord.[70] The drug does not produce any significant respiratory depression. There is also mounting evidence that dexmedetomidine has protective effects against ischemic and hypoxic injury.[47]

The onset of action occurs after approximately 15 minutes of IV injection, the drug distribution occurs rapidly from the brain, leading to a short terminal half-life. Hepatic metabolism by glucuronidation leads to production of inactive metabolites. Dose reductions are required in the presence of both renal and liver disease.[47] The drug is apparently remarkably safe when administered as the sole agent, with oversedation which spontaneously recovers on drug discontinuation being the only reported adverse event on accidental infusion of large doses.[71] However, on coadministration with sympatholytic or cholinergic agents in the settings of vagal stimulation, there is a risk for excessive bradycardia and even sinus arrest.[47]

Dexmedetomidine can provide excellent sedation without respiratory depression during fiberoptic intubation or other difficult airway procedures. In these settings, it has added benefits of decreasing saliva production and airway secretions.[72–74] In high infusion doses, it has been used as a sole agent to anesthetize patients with tracheal stenosis, as it preserves spontaneous ventilation.[74] Currently, the drug is approved by the United States Food and Drug Administration (US-FDA) for use up to 24 hours in mechanically ventilated patients. Recent studies have indicated dexmedetomidine may be safely used as infusion with durations exceeding 24 hours.[70,75,76]

In a recently published prospective,multicenter, randomized double blind trial comparing midazolam and dexmedetomidine, patients in the dexmedetomidine group had a significantly lesser duration of mechanical ventilation and had significantly lesser prevalence of delirium during treatment. The time within the target sedation levels was comparable between the groups. The most important treatment related adverse effect of dexmedetomidine was bradycardia.[70]

Dexmedetomidine may be preferred sedative agent for ICU patients, because of its beneficial effects. If patient has bradycardia, LV dysfunction or in settings when deep sedation is required, other agents may be more appropriate.

Volatile Anesthetic Sedation

Volatile anesthetic agents offer the advantage of quick onset and offset of action and ease of titration of effect. The route of delivery and elimination are primarily the lungs, therefore hepatic or renal dysfunction has little impact on the duration of effect and emergence times. Excellent control of the drug effect can be done by monitoring the end-tidal concentration or fraction. Adverse effects can be immediately reversed by decreasing the inspired concentration of the agent. Isoflurane, desflurane and sevoflurane have been used for ICU sedation. The major obstacles to the use of volatile anesthetics for ICU sedation are cost, concerns for environmental pollution and the need of anesthetic expertise. The requirement of a cumbersome circuit for delivery hinders their use.

Recent technological advances like a new and fairly simple device, the ‘‘Anesthetic Conserving Device’’ (AnaConDa, Hudson RCI, Uppslands Vasby, Sweden) allow the infusion of liquid volatile anesthetic through the breathing circuit of a standard ICU ventilator. A semi-closed rebreathing circuit is created which retains 90% of the inhaled anesthetic.[47]

The use of volatile anesthetic sedation has demonstrated shorter emergence times (isoflurane vs midazolam or propofol), shorter times to extubation and hospital LOS postcardiac surgery (sevoflurane vs propofol), better cognitive functions after emergence (desflurane vs propofol) and a trend towards lesser propensity to develop delirium (isoflurane vs midazolam).[77–82] Volatile anesthetic sedation may become an attractive alternative to routine use of IV sedative agents in the ICU in future.

Peripherally Acting Mu-opioid Receptor (PAM-OR) Antagonists

Opioid use in the ICU is associated with a number of gastrointestinal side effects like constipation, ileus and delayed gastric emptying. PAMORAs are a novel class of drugs which do not cross the blood-brain barrier to antagonize the central effects of opioids, thereby preserving the analgesic effects. They antagonize the peripheral side effects of opioids, importantly constipation and ileus.[47]

Methylnaltrexone and Alvimopan are currently the FDA approved PAMORAs. Subcutaneous methylnaltrexone is approved for the relief of opioid-induced constipation and oral alvimopan, to facilitate the return of gut dysfunction after anastomotic bowel surgery. This class of drugs may prove to be of great therapeutic potential in the management of patients in the ICU particularly in those requiring frequent and prolonged administration of opioids.

Use of Patient Targeted Sedation—Analgesia Protocols and Daily Interruption of Sedation

Use of Sedation Protocols or Algorithms

Use of protocols for ICU sedation and analgesia involves assessment of pain and levels of sedation, using validated assessment tools and integration of the same into an algorithm according to which changes in the medication dosage are done.[83] Patient management regarding ICU sedation and analgesia is multidisciplinary; therefore, this area is particularly well suited to a protocolized and structured approach.

The primary aim of these approaches is to avoid accumulation of medications and their active metabolites which can be associated with a slower rate of recovery from critical illness. Critically ill patients are susceptible to prolonged effects of sedative analgesic medications, owing to a number of factors like alterations in volume and protein binding status and presence of renal or hepatic dysfunction and other factors.[84] Use of protocols has also been associated with reduction in diagnostic studies for unexplained changes in mental status, a reduction in the side effect of medications and reduction in hospitalization costs.[66] Less patient ventilator dys-synchrony and decreased incidence of VAP have also been found to be associated with the use of a sedation algorithm or protocol.[85,86]

The development and design of the protocol should be multidisciplinary, so should be the implementation.[87] Treatment goals should be established and frequent assessments done. Validated scales should be used for the assessment of pain and agitation. Evidence based selection of medication and patient focussed approach should be used. The protocol should be robust enough to effectively control pain and agitation, but avoid oversedation. Finally, multidisciplinary acceptance of the protocol and its integration into routine care should be achieved.

In most algorithms, it is the bedside nurse who is actually responsible for the implementation of the protocol interventions. The availability of a clinical pharmacist to ensure adherence is not possible at all centers. The addition of a daily intervention of involving a clinical pharmacist to ensure sedation protocol adherence led to a significant reduction in the duration of mechanical ventilation in one study.[88]

Most algorithms incorporate the management of pain and agitation within a single algorithm. First focus is towards the detection of pain and adequate analgesia, followed by sedative therapy as required. This strategy has been termed as ‘‘analgesia-first’’ or “A1” approach by some authors in which sedatives are administered only after aggressive analgesic strategies.[89]

The protocols used in the various published studies range from simple to complex algorithms. The simpler protocols make use of a sedation scale to make objective assessment and simple instructions regarding medication selection and dose of administration. Complex protocols have targeted a number of domains, like the assessment of the intensity of pain, sedation, patient ventilator dys-synchrony and delirium.[87]

Analgesia Based Sedation Protocols/Co-sedation

Recently, there has been interest in strategies that focus primarily on provision of analgesia, with addition of a sedative/hypnotic agent as and when required - termed as “analgesia based” or “co-sedation” strategies. Two approaches have been used in trials. In one, initially titration of analgesic infusion is done prior to the addition of a sedative drug. In the other approach, co-infusion of both the sedative and analgesic drug has been done.

Analgesia based strategies have been demonstrated to reduce the duration of mechanical ventilation,[90] lead to better sedation with more “on-target” sedation,[85] less patient ventilator asynchrony[85] and faster awakening for neurological assessment in neurotrauma patients.[91]

Analgesia-Delirium-Sedation Protocols

A shorter duration of mechanical ventilation was observed when pain (visual scale), agitation (RASS) and delirium (CAM-ICU) were assessed as a part of the single protocol.[92]

Numerous controlled trials comparing protocols with usual care have supported the use of structured approaches. However, the ideal structure of the approach is not clear, as a multitude of approaches have been used. The common principle however remains to reduce oversedation.

A longer ICU LOS has been reported following the use of a sedation algorithm.[93] However, such reports are scarce and the benefits of using sedation protocols or algorithms have been consistently reported. Centers can have their own approaches according to the available infrastructure, with a common goal of the approach being drug administration reduction of oversedation and using an intermittent strategy vs continuous infusion. Also, the algorithm should be easy to understand and implement.

Daily interruption of sedation (DIS): The underlying principle of this strategy is to provide a daily drug free period to minimize the chances of drug accumulation and allow the patient to awaken. A reassessment can be done of the actual level of pain, level of agitation and the readiness of the patient to tolerate spontaneous breathing. The strategy incorporating daily interruption of sedative (midazolam or propofol) and analgesic (morphine) medications until the patient was agitated or able to follow simple tasks, led to significant reductions in the duration of mechanical ventilation, use of less number of diagnostic tests for unexplained altered level of consciousness and a shorter ICU LOS.[66]

DIS has also been associated with a reduction in the risk of several well known complications of critical illness like ventilator-associated pneumonia, upper GI bleed, bacteremia, cholestasis, barotraumas, venous thromboembolism and sinusitis requiring surgical intervention.[94] A careful clinical observation is required while practicing the DIS strategy. If the patient develops signs of increasing distress and agitation, a bolus administration of the drugs can be done and infusions restarted at half the previous rates. Patients who after the daily interruption of medications, do not develop signs of increased agitation and are awake, should have their drugs restarted only when needed, not routinely.

Combining DIS with SBT (Spontaneous breathing trials): A low MIP was found to be independently associated with deeper levels of sedation in mechanically ventilated patients.[95] It is therefore possible that improved levels of consciousness may be associated with greater chances of tolerating spontaneous breathing and consequent liberation from mechanical ventilation.[96]

Concerns with DIS Implementation: Because of the abrupt awakenings which occur in patients with DIS, there have been a few practical concerns such as a rebound increase in agitation when the medications are stopped, with possible related events like self removal of catheters, violent behavior and patient ventilator asynchrony.[66, 67, 96]

Another concern has been the adverse neuropsychiatric impact of daily interruption of sedation, leading to abrupt awakenings in the critically ill individuals. However, DIS has been shown to be associated with no adverse neuropsychiatric outcomes and has demonstrated a trend towards a reduced occurrence of post-traumatic stress disorder (PTSD) at 1 year.[97]

Awakenings during DIS are associated with an adrenergic surge, with consequent increases in heart rate, blood pressure and levels of circulating catecholamines, raising concerns regarding the implementation of this strategy in patients with an underlying risk of coronary artery disease (CAD). In an observational study, DIS was not shown to increase the number of cardiac ischemic events in patients with underlying risk factors for CAD.[98]

Although DIS appears to be a relatively safe and effective strategy, extreme caution should be exercised in certain group of individuals like those with a history of alcohol or substance abuse as precipitation of withdrawal in them can lead to undesirable consequences.[5, 45] Caution should also be exerted in patients with conditions like hypertensive emergencies and status asthmaticus, in whom the stress response may have detrimental consequences.[5]

Recent Developments and Novel Approaches

"No Sedation" Protocols

The no sedation protocol in a recent single center trial, on 140 critically ill adult patients relied on the intermittent administration of morphine without any continuous infusion of sedative or analgesic agents.[99] Protocol violation with administration of sedative agents was required in 10 patients mostly to permit adequate ventilation in ARDS.[100] Complications did not differ between the groups but delirium was more frequent in the no sedation group (DSM-IV criteria) and there was a need for an extra person at the bedside to comfort and reassure patients more often in the intervention group than in the control group (20% *vs* 5%).

This strategy appears promising but findings will need to be confirmed in large, multicenter trials, before it can be widely adopted. Nonetheless, this approach may provide a shift in paradigm for the future research trials to using as less sedation in the ICU as possible.

Patient Controlled Sedation (PCS) for Mechanical Ventilation

Based on the demonstration that patients who self-administer analgesics, i.e. patient controlled analgesia (PCA), eventually have lesser drug requirements and achieve better symptom control, it was hypothesized that PCS in mechanically ventilated patients, an untested approach till now, might lead to reduced sedative requirements, and eventually may be associated with better clinical outcomes. The safety and adequacy of this novel approach was tested in a recent single center pilot study, using dexmedetomidine given as a basal infusion coupled with patient triggered boluses, for 24 hours.[101] In a small sample size of 17 mechanically ventilated patients who had stable or improving pulmonary status, PCS was rated favorably for self-management of anxiety. The level of relaxation obtained and comfort in self-administration of sedative medication were acceptable.

This study demonstrated the feasibility of PCS using dexmedetomidine in mechanically ventilated patients with improving pulmonary status, those who have minimal sedative requirements and able to comprehend the instructions for pump use.

Sedation and Immunity

Available evidence links benzodiazepine and propofol use with suppression of the innate immune response and an unclear effect on the adaptive immune response.[102]

Opioids on the other hand, lead to suppression of both innate and adaptive immune responses. Chronic use of morphine leads to a shift to Th2 cytokine predominance.[103] Such a shift has also been observed in the later stages of sepsis and therefore opioids may contribute to increased incidence of infections and immunosuppression in the critically ill patients.

Dexmedetomidine may have particularly beneficial immunologic effects as an ICU sedative agent. As compared to other sedatives, Dexmedetomidine has superior anti-inflammatory effects, improves macrophage function and has antiapoptotic effects.[102, 104] There also are indications that the choice of sedative may be of great importance in patients with sepsis. In a subgroup analysis of the MENDS study, dexmedetomidine demonstrated a 70% mortality benefit at 28 days, as compared to lorazepam based sedation with a lesser duration of mechanical ventilation and more delirium free days in dexmedetomidine treated patients.[75]

Global Use of Sedation Scales and Protocols

Surveys done prior to the SCCM "Clinical practice guidelines for the sustained use of sedatives and analgesics in the critically ill adult" in 2002 revealed that sedation assessment was performed in less than 50 % of ICU's all over the globe.[21] Even after the publication of SCCM guidelines, use of sedation scales for objective assessment in the ICU's remains disappointingly low.

In a study of 1381 patients in 44 French ICU's in 2004, a sedation protocol was being used in 36% ICU's and a sedation or pain assessment scale in approximately 50% of the patients receiving sedative analgesic medications. Procedural pain was specifically managed in less than 25% of the patients. DIS was not being used in any of the ICU'S. 40 to 50% of the assessed patients were under deep sedation.[11]

Widespread implementation of sedation and delirium assessment tools is achievable but there are several practical issues like implementation by the nursing staff-lack of time concerns and lack of confidence.[105]

Sedation and Analgesia Withdrawal

Symptoms of acute withdrawal syndrome can occur following prolonged administration of these agents in the ICU. Also, frank withdrawal symptoms may not be obvious all the time, patient may manifest clinical signs only. Withdrawal symptoms and even physical dependency have been documented, particularly in critically ill pediatric population with almost any agent.[106,107] In a retrospective study of patients in an adult trauma/surgical ICU, 32% of the patients requiring more than 7 days of ICU care developed acute withdrawal syndrome, with administration of sedative and analgesic medications potentially implicated for the same.[108]

Development of withdrawal syndrome may have potential deleterious consequences and has also been linked to the development of ICU delirium.[5] SCCM guidelines recommend considering the potential for opioid, benzodiazepine and propofol withdrawal after high doses or more than approximately seven days of continuous therapy and systematic tapering, to prevent withdrawal symptoms. During the period of recovery from critical illness, a careful watch should be kept for signs and symptoms, which may be nonspecific indicators of withdrawal like hypertension, tachycardia, fever, nausea, insomania, delirium, agitation and diaphoresis. Gradual reduction of sedative and analgesic medications should be considered in patients thought to be at high risk, particularly the pediatric patients.

Delirium in the ICU

Delirium is characterized by an acutely changing or fluctuating mental status, inattention, disorganized thinking and an alteration in the level of consciousness. Agitation may or may not be there. Delirium occurs in approximately 35 to 80% of the ICU patients, is independently associated with a longer hospital LOS, increased mortality and greater economic costs.[3,109,110] Delirium assessment using validated assessment tools is seldom performed in the ICU's.[111]

Delirium can be classified into three subtypes: hypoactive, hyperactive, or mixed.[112] Hypoactive delirium is associated with the worst prognosis. It is characterized by psychomotor retardation, difficult to detect unlike hyperactive delirium which is easily recognized.

Assessment of Delirium in the ICU

Routine assessment of delirium in critically ill patients is recommended even in those who are calm and apparently not agitated. The gold standard criteria for the diagnosis of delirium is the clinical history and examination. This method of assessment is usually not possible in critically ill and ventilated subjects because of the inability to speak and write and therefore other tools for assessment of ICU delirium have been developed (Table 150.9). These tools can be used for delirium assessment by trained ICU staff and not necessarily by psychiatrists.

TABLE 150.9: Delirium assessment tools in the ICU

- Confusion assessment method for the intensive care unit (CAM-ICU)[113]
- Intensive care delirium screening checklist (ICDSC)[114]
- Cognitive test for delirium[115]
- Cognitive test for delirium – abbreviated version[116]
- Neelon and champagne confusion scale[117,118]
- Delirium detection score[119]
- Nursing rating scale for ICU delirium

The confusion assessment method for the intensive care unit (CAM-ICU) and cognitive test for delirium are interventional tools based on direct testing of the patient's state by the rater, whereas ICDSC and Nursing scale for delirium are observational tools based on the observation of certain patient behaviors by the rater.[5]

The CAM-ICU and ICDSC have been extensively validated. The ICDSC also offers an advantage of detection of "subsyndromal" delirium which over the course of time may progress to overt delirium.[5, 120] In subsyndromal delirium, patients exhibit one or more delirium symptoms without meeting the criteria for full-blown clinical delirium. SCCM guidelines[1] mention CAM-ICU as a promising tool for the assessment of delirium in ICU patients. The components of CAM-ICU include the observation of an acute onset of mental status change or a fluctuating mental status, inattention, disorganized thinking and an altered level of consciousness. The tool on an average takes approximately 2 minutes to complete and is easy to use.

Prevention and Treatment of Delirium

Delirium prevention in ICU: The strategies for prevention of delirium may be divided into nonpharmacologic, pharmacologic and combined approaches.[109] Use of certain nonpharmacologic approaches have demonstrated favorable outcomes in non ICU patients.[121,122] These strategies based on the underlying principles of reorientation, communication, mobilization and minimization of drug exposure may be used in ICU subjects too. Pharmacologic approaches to reduce delirium in the ICU have not been evaluated extensively. No studies have been done to assess the role of prophylactic haloperidol in the ICU patients. Dexmedetomidine appears to be a promising drug which may assume an important role in ICU delirium management. In a recent RCT, the prevalence of delirium was significantly lower in dexmedetomidine-treated patients: 54% versus 76.6% in midazolam-treated subjects ([95% CI, 14%–33%]; p<.001).[70]

A combined approach using both pharmacologic and nonpharmacologic methods has been tried, with a reduction in subsyndromal delirium.[123] These strategies are difficult to implement, may not be appropriate for use in all patients.

Treatment of delirium: Pharmacologic therapy remains the mainstay of management of delirium in the ICU. Attention should first be paid to the recognition of an underlying correctable cause. Antipsychotic agents are the most commonly used and recommended drugs for the management of delirium. Both conventional and atypical antipsychotic agents are apparently effective.

Haloperidol, olanzapine and quetiapine have been used in the management. Studies evaluating the use of antipsychotics in ICU are limited. In a small prospective trial, both olanzapine and haloperidol were found to be equally efficacious in controlling delirium. Olanzapine, however was associated with lesser extrapyramidal side effects.[124]

According to the SCCM guidelines, Haloperidol is the preferred agent for the treatment of delirium in critically ill patients. There is however no consensus on the optimal dosing and the treatment regimen of haloperidol. Haloperidol is usually administered by intermittent IV injections. Initially, a starting dose of 2 mg IV can be administered followed by repeated doses (doubling the previous dose) every 15–20 min. The loading dose is administered till the control of acute agitation.[1, 125] After the control of acute agitation, scheduled intermittent doses (25% of the loading dose) may be administered 6 hourly and then gradually tapered off.

Monitoring should be done for electrocardiographic changes (QT interval prolongation and arrhythmias) when receiving haloperidol.[1] Development of Extra-Pyramidal Syndrome (EPS) is another known complication of administration of neuroleptic agents. If EPS develops, haloperidol should be stopped and a trial of diphenhydramine or benztropine should be given.

Prior to hospital discharge, cognitive function assessment is preferable in all the patients with proper neuropsychiatric advise and rehabilitation during follow-up, if required.

In conclusion, teamwork and patient focussed care play a key role in the management. Adequate pain relief should always take priority oversedative administration and adequacy of analgesia should be determined using patient self report, if possible. Consequences of inappropriate sedation and pain relief have been well recognized, thereby necessitating frequent and structured assessment of pain and agitation in the ICU patients using validated assessment instruments. The choice of sedative and analgesic agent should be done keeping the individual patient clinical characteristics in focus. Protocol based sedation and DIS are strategies which are backed up with good quality evidence to be associated with better patient outcomes. Institutions should devise protocols, depending on the feasibility and ease of use according to the available resources. Delirium assessment using validated delirium assessment tools should be included as a part of the patient assessment and delirium should be appropriately managed.

Weaning from Mechanical Ventilation

Ajmal Khan, Karthik Gnanapandithan, Ritesh Agarwal

INTRODUCTION

Patients require mechanical ventilatory support when the ventilatory and/or gas exchange capabilities of their respiratory system fail as a result of processes both within the lung as well as in other organ systems. Once the cause of respiratory failure starts improving, then the ventilatory support needs to be discontinued either gradually or abruptly. Weaning is a process of abruptly or gradually withdrawing ventilatory support, and includes discontinuation of Mechanical Ventilation (MV) and removal of artificial airway if any. Difficulty and complexity in weaning can be estimated by the time spent in the weaning process which represents 40 to 50% of the total duration of mechanical ventilation.[1] In patients with more slowly resolving lung disease, time spent in the weaning process is likely to be much higher. Approximately 70 to 75% of mechanically ventilated patients whose underlying cause of respiratory failure has either improved or resolved can be discontinued abruptly from mechanical ventilation.[2,3] The remaining patients will need gradual and progressive withdrawal from mechanical ventilation.

The determinants of assessing a patient's readability to wean and the best weaning technique currently remain unclear. The process of weaning begins when the patient has started recovering from acute respiratory failure. Thereafter, clinical, biochemical and respiratory assessments are frequently performed to determine the patient's readiness for discontinuation of ventilator support and extubation. The assessment for weaning generally begins from the first day of ventilation, and Fig. 151.1 shows the stages of weaning process. Not only delayed weaning is associated with increased costs of ICU care but the risks of nosocomial pneumonia, cardiac morbidity and death is also increased. On the other hand, a premature weaning attempt carries the risk of compromised gas exchange, high incidence of nosocomial pneumonia, difficulty in re-establishing the airway and 6–12 fold increased risk of mortality.[4]

Improvement of the underlying cause of acute respiratory failure
Assessment of readiness to wean
Spontaneous breathing trials/ pressure support reduction
Extubation
Successful weaning
Reintubation

Fig. 151.1: Stages in weaning from ventilation

Weaning can further be classified as: (a) Simple weaning: Initiation of weaning to successful extubation on the first attempt without difficulty is simple weaning. It carries a good prognosis with an ICU and in-hospital mortality of approximately 5% and 12%, respectively;[5,6] (b) Difficult weaning: Failure to tolerate initial

Spontaneous Breathing Trial (SBT) successful weaning requiring up to three SBTs or up to 7 days from first SBT and (c) Prolonged weaning: Failure of at least three SBT or takes more than 7 days after the first SBT is prolonged weaning. Both difficult and prolonged weaning increases duration of hospital stay and consequently carries an ICU mortality of approximately 25%.

PATHOPHYSIOLOGY OF WEANING

In a patient being mechanically ventilated, a complex interaction of the control of breathing, lung and chest wall mechanics, respiratory muscles, gas exchange properties of the lung and the cardiovascular hemodynamics determines the process and timing of weaning. Disturbance at any level can potentially lead to weaning failure.

Altered Control of Breathing

Central drive may be impeded by metabolic alkalosis, MV itself or the use of sedative/hypnotic medications. Failure of breathing control leading to weaning failure can occur due to either structural lesion like brainstem strokes or central apneas or metabolic factors such as electrolyte disturbances or sedation/narcotic usage.[7–9] Additionally, structural or metabolic abnormalities including drugs affecting the peripheral nerves will also result in altered afferent or efferent output and ventilator dependence.[10, 11]

Altered Respiratory Mechanics

Physiological variables most commonly altered during weaning process are the resistance, elastance and air trapping. Four factors account for the increase in resistance, and these are increased inspiratory flow, decrease in lung volume, accumulation of secretions and bronchoconstriction.[12–14] Low respiratory system compliance occurs due to stiff chest wall, stiff lungs, flooded or atelectatic alveoli. The presence of auto-Positive End Expiratory Pressure (auto-PEEP) increases the pressure gradient needed to inspire irrespective of whether patient is triggering the ventilator or spontaneously breathing.[15, 16] This increase in inspiratory threshold raises the work of breathing and leads to weaning failure.[17]

Respiratory Muscle Dysfunction

Respiratory muscles weakness occurs commonly in the critically ill patients as a consequence of:

- Atrophy and remodeling from inactivity[18]
- Critical illness neuropathy and myopathy[19,20]
- Drugs (neuromuscular blockers, aminoglycosides and corticosteroids)[21–23]
- Metabolic factors like nutrition, electrolytes and hormones
- Imbalance between respiratory muscle capacity and the load[24-26]

The load on the ventilatory muscles depends on the ventilation demands and respiratory system mechanics (i.e. primarily compliance and resistance). Ventilatory demands are increased as a consequence of increased oxygen demands during sepsis, anemia, pulmonary embolism and increased dead space in patients with obstructive defects. Likewise, compliance worsening due to lung edema, infection, inflammation, fibrosis and chest wall abnormalities such as edema or surgical dressings or increased resistance secondary to bronchoconstriction and airway inflammation and secretions will alter the lung mechanics and consequently increase the respiratory load. Additional load also can be imposed by narrow endotracheal tubes and by insensitive or poorly responsive ventilator demand valves.

Inadequate nutrition causes increased protein catabolism leading to a loss of muscle performance.[27, 28] Similarly, in semi-starvation conditions, normal hypoxic ventilatory response and the hypercapnic ventilatory response deteriorate.[29] In contrast overfeeding leads to excess CO_2 production that may impair the ventilator withdrawal process by further increasing the ventilation loads on ventilatory muscles.[30,31]

Electrolyte imbalance most importantly deficiency of phosphate and magnesium has also been shown to impair ventilatory muscle function.[32–35] Severe hypothyroidism and myxedema directly impair diaphragmatic function and blunt ventilatory responses to hypercapnia and hypoxia.[36,37] Beside thyroid hormone, insulin/glucagon and adrenal corticosteroids are also important for optimal muscle function and deficiency of any of them may cause respiratory muscle dysfunction.

Cardiovascular Performance

All the ventilatory work during respiration is performed by respiratory muscle without getting fatigue. Thus they depend on an efficient transport of oxygen by the cardiovascular system. Several groups of investigators have drawn attention toward the potential for weaning process to induce ischemia or heart failure in susceptible individuals with limited cardiac reserve.[38–42] These cardiovascular dysfunction during the transition from MV to spontaneous breathing occurs due to increased metabolic and circulatory demands, increased venous return due to displacement of blood from the abdomen to thorax by contracting diaphragm and increased left ventricular afterload imposed by negative pleural pressure swings.

OUTCOME OF WEANING

Weaning failure is defined as either the failure of the weaning process or intolerance to the SBT or the need for reintubation within 48 hours following extubation. *Intolerance to SBT* is defined by objective indices of failure, such as tachypnea, tachycardia, hypertension, hypotension, hypoxemia or acidosis, arrhythmia and subjective indices, such as agitation or distress, depressed mental status, diaphoresis and evidence of increasing effort.[2, 3, 5, 43]

ASSESSMENT FOR WEANING

The evaluation of patients' readiness for weaning begins with the resolution of respiratory failure and/or the disease entity that prompted the initiation of MV as well as the presence of a basic level of physiological readiness like intact airway reflexes, afebrile and cardiovascular stability. The patient's capacity to breathe spontaneously is often underestimated by the subjective criteria and clinical judgment. Stroetz et al. showed, intensivists could not accurately predict patient tolerance of a 1-hour period on minimal pressure support.[44] Similarly, Afessa and colleagues reported that practitioners in the critical care failed to accurately forecast 3-day and 7-day weaning outcome for mechanically ventilated patients in a medical Intensive Care Unit (ICU). [45]Thus, there is an obvious rationale that predicting readiness of successful weaning from MV needs to be based on objective predictors that can be applied in clinical decision making. To facilitate the process of assessment, various objective criteria have been established. Nevertheless, the objective criteria only needs to assist physician's clinical judgment and many patients may be weaned even if they do not fulfill these criteria. These criteria are broadly described in Table 151.1.

Indices to Predict Weaning Success Prior to SBT

Even prior to the implementation of an SBT, there are certain simple indices that are used to predict the outcome of the weaning trial.

TABLE 151.1: Objective criteria to facilitate assessment of weaning

A. Patient parameters

1. Improvement of the basic underlying cause
2. Awake, alert and cooperative
3. Hemodynamically stable
4. Respiratory rate <30/minute
5. No effect of sedation/neuromuscular blockade
6. Minimal secretions (generally less than 2 hourly suctioning requirement)
7. Good nutritional status

B. Ventilator parameters

1. Spontaneous tidal volume (TV) >5–8 ml/kg
2. Vital capacity (VC) >10-15 ml/kg
3. PEEP requirement <5 cm of H_2O
4. Static compliance >30 ml/cm of H_2O
5. Minute ventilation <10 L
6. Ratio of dead space volume to tidal volume (VD/VT) <60%
7. Maximal Inspiratory Pressure (MIP/Pimax)
8. Negative inspiratory force

C. Oxygenation criteria

1. $PaCO_2$ <50 mm Hg with normal pH
2. PaO_2 >60 at FiO_2 0.4 or less
3. SaO_2 >90% at FiO_2 0.4 or less
4. PaO_2/FiO_2 >200
5. $P(A\text{-}a)O_2$ <35 mm Hg at FiO_2 of 1.0

Simplified Weaning Index (SWI)[46]

$$\text{SWI} = \frac{F_V \times (\text{IP} - \text{PEEP})}{\text{MIP} \times 40} \times PaCO_2$$

A SWI less than 9 per minute is 93% predictive of successful weaning in the patient whereas a SWI greater than 11 per minute is 95% predictive of weaning failure.

CROP Index (Compliance, Rate, Oxygenation, Pressure)

The CROP index is an integrative index incorporating several measures of readiness for liberation from mechanical ventilation, such as dynamic respiratory system compliance (Crs), spontaneous breathing frequency (f), arterial to alveolar oxygenation [partial pressure of arterial oxygen (PaO_2)/partial pressure of alveolar oxygen (PaO_2)], and PImax in the following relationship:

$$\text{CROP Index} = \frac{C_{dyn} \times \text{MIP}}{f} \times (PaCO_2 / PACO_2)$$

CROP index assesses the relationship between the demands placed on the respiratory system and the ability of the respiratory muscles to handle them.[47] A CROP Index greater than 13 ml per breaths per minute is predictive of weaning success.[47]

Rapid Shallow Breathing Index (RSBI)

Tobin and colleagues[30] first noted that patients with weaning failure developed significantly more rapid and shallow breathing than those who succeeded.[48] Subsequently, the same authors in a prospective study demonstrated that the ratio of frequency to tidal volume [Rapid Shallow Breathing Index (RSBI)] obtained during the first minute of a T-piece trial and at a threshold value of ≤105 breaths/minute/l was a significantly better predictor of weaning outcomes than other 'classic' and commonly used parameters.[47] It has a sensitivity and specificity of 97% and 65% respectively.[47] However, in later studies it was noted that RSBI has certain shortcomings, like it can produce excessive false positive predictions and has a less predictive power in COPD, elderly and in patients who needs ventilatory support for more than 8 days.[40, 49–51] One option to overcome this discrepancy is to use a SBT of 30–120 minutes in a patient who has RSBI of ≤ 105 breaths/minute/l to further assess patient readiness for liberation from mechanical ventilation.

Another important limitation RSBI is that the RSBI threshold can be influenced by the ventilatory support settings, the experimental conditions, and the patient population. When measured during trials of Pressure Support Ventilation (PSV), the RSBI has a limited value in predicting weaning outcome.[44] El-Khatib et al. reported that in the same patient's population, different ventilatory support settings can have a significant influence on the RSBI values. They showed there was a significant decrease in RSBI during a trial of PSV, Continuous Positive Airway Pressure (CPAP) on 40% oxygen and CPAP on room air as compared to a trial of T-piece for 1 minute in a spontaneously breathing patient at room air.[52,53] Thus, RSBI should only be adapted if the determination of the index is performed where patients were disconnected from the ventilator and spontaneously breathed room air for one minute because it can easily be applied at the bedside, and can be readily utilized to identify patients who are candidates for SBT.

Muscle load indices: These require more sophisticated measurements such as pleural pressure (estimated from esophageal pressure) to calculate the Pressure Time Product (PTP) and Pressure Time Index (PTI).[54] PTI can be a useful predictor of fatigue when it is more than 0.1.

TECHNIQUES OF WEANING

Once the patient has passed the predictor test they can immediately be extubated, however, because of the high rates of post-extubation distress and reintubation rates of approximately 40%, this approach is not recommended and there is need for a formal weaning trial before extubation.[55] Weaning trials also improves the patient's likelihood of tolerating extubation because of the improved reconditioning of the respiratory muscles. The major techniques used for weaning from MV is simply to initiate a trial of unassisted spontaneous breathing in the form of either a T-piece trial, low level CPAP trial, SIMV trial, PSV trial or a combination of these trials. As long as the principle of "Do Not Exhaust" is followed, the decision on which trial to use remains largely a matter of physician preference and the local protocols. SBTs are used to test readiness for weaning as well as to implement a weaning protocol that involves increasing periods of unsupported spontaneous breathing interspersed with periods of full ventilatory support.

Spontaneous Breathing Trails (SBTs)

The SBT is the oldest weaning technique wherein the patient is directly removed from the ventilator and put on T-piece with supplemental oxygen. It is mainly used for the assessment of readiness for extubation but it can also be used for weaning in which the length of the each SBT is gradually increased with alternating period of gradually decreasing ventilatory support. The SBT can be conducted without removing the patient from the ventilator which has the added advantage of quickly reinstitution of the ventilatory support in the face of SBT failure. It can be performed with no positive pressure applied to the airway with a low level of CPAP (5 cm H_2O) or PS (7 cm H_2O). Optimal SBT duration has been examined in two studies suggesting that 30 minutes is equivalent to 120 minutes with either T-piece or PSV.[6, 56] Optimal SBT duration may depend upon the duration of ventilation or the underlying cause for respiratory failure. An investigation of 75 patients with Chronic Obstructive Pulmonary Disease (COPD), ventilated for 15 or more days, found a median time to trial failure of 120 minutes.[57] Therefore, in some patients the SBT should be extended to at least 120 minutes. However, we generally use an SBT of at least 60 minutes.

A potential concern about the SBT is safety. Although unnecessary prolongation of a failing SBT may precipitate muscle fatigue, hemodynamic instability, discomfort or worsened gas exchange, however, there are no data showing that SBTs contribute to any adverse outcomes if terminated promptly when failure is recognized.[25, 58–60] The detrimental effects of ventilatory muscle overload during failing SBT often occurs early, thus, the initial few minutes of an SBT should be monitored closely and judiciously before continuing the SBT.[43,47,61] Thereafter, SBT can be continued for at least 30 minutes but not greater 120 minutes to assure maximal sensitivity and safety.

Failure of SBT is defined by the presence of tachypnea, tachycardia, arrhythmia, hypertension, hypotension, hypoxemia or the subjective evidence of agitation or distress, depressed mental status and diaphoresis.[2,3,5] A failed SBT should prompt a search for other causes or complicating factors and once the medical management is optimized further SBTs over a day is not expected to be helpful. Since failed SBTs are often due to persistent mechanical abnormalities of the respiratory system especially muscle fatigue that are unlikely to reverse rapidly.[58,59,62] Esteban et al. specifically addressed this issue and provided strong evidence that twice-daily SBTs offer no advantage over a single SBT and thus next SBT should be given after 24 hours only.[3]

Pressure Support Ventilation

Gradual reduction of PS is commonly utilized and is the sole mode of MV used during the weaning process in 21% of patients.[63] It is a pressure limited ventilation that recognizes the patient's inspiratory effort, ensures appropriate delivery at the time of inspiration and cycles to the expiratory phase without need for active patient exhalation. During PSV, breath is flow cycled to the expiratory phase when the flow decelerates to the 5 L/min or 25% of the peak inspiratory flow. The disadvantage is that flow deceleration is determined by resistance and compliance of the respiratory system. In patients with airflow obstruction, flow decelerates slowly. The flow needed to cycle may not be reached, stimulating active exhalation. During weaning, PSV is started at around 10–20 cm of H_2O and reduced by 2–4 cm H_2O at least twice daily till very low values can be tolerated. PSV is useful to counteract the extra work imposed by breathing through an endotracheal tube.

Synchronized Intermittent Mandatory Ventilation (SIMV)

Breathing during the SIMV mode is either mandatory ventilator controlled or spontaneous. Mandatory breaths are synchronized with the patient's effort that is either volume or pressure controlled. Spontaneous breathing is pressure supported. Weaning by SIMV is achieved by gradually decreasing the mandatory breathing rate by 2–4 breaths per minute and allowing the patient for spontaneous breathing effort to maintain the minute ventilation. As traditionally believed, respiratory muscle rest does not occur during mandatory breath of SIMV. In fact, respiratory center output and respiratory muscle activity is as great during the mandatory breaths as the spontaneous breaths.[64, 65] A comparative chart of different modes of weaning is given in Table 151.2.

TABLE 151.2: Comparative analysis of three commonly used modes for weaning

	T-piece	*SIMV*	*PSV*
Work quantity	All or none	Adjusted by no. of mandatory breaths	Adjusted by level of given pressure
Tidal volume	Determined by patient	Set by clinician	Patient interacts with applied pressure
Minimum minute ventilation	Not assured	Assured	Not assured
Synchrony	Regular periods of irregular load	Regular load	Constant
Patient comfort	Least	Intermediate	Most
Equipment complexity	Simple	Intermediate	Maximum

Continuous Positive Airway Pressure (CPAP)

The CPAP by itself is not a mode as it does not provide any inspiratory support. However, CPAP when applied during spontaneous breathing in patients with acute respiratory insufficiency reduces mean intrathoracic pressure has beneficial effects on right and left ventricular performance improves oxygenation and reduces the work of breathing.[66, 67] Bailey et al. randomized patients to receive CPAP or T-piece trials prior to extubation and observed no significant difference in oxygenation or time spent on mechanical ventilation.[68] Squadrone et al., in a multicenter randomized controlled trial, observed that CPAP compared to oxygen supplementation substantially reduced the reintubation rate.[69] Although combinations of CPAP and PSV are commonly applied during the weaning period, there is also a lack of prospective randomized controlled trials to suggest that CPAP is superior to other techniques such as PSV alone or T-tube in the process of weaning from invasive mechanical ventilation.

Role of Noninvasive Ventilation (NIV) in Weaning

Mechanical ventilation once instituted can be withdrawn abruptly in majority of the patients. However, approximately one third of the patients still require gradual weaning.[2,3] Among them 13 to 19% needs reintubation because of post-extubation respiratory failure.[43,70] Although the need for reintubation may be a marker of increased severity of illness, it is an independent predictor of mortality.[71,72] Therefore, any strategy that prevents the development of respiratory failure after extubation and subsequent reintubation are needed. One such strategy is the application of NIV that has been applied in patients with difficult weaning as well as used for the prevention and treatment of post-extubation respiratory failure. In patients with chronic respiratory failure especially those due to COPD, the application of NIV has been shown to decrease endotracheal and MV duration, the ICU and hospital stays, the incidence of nosocomial pneumonia, the need for tracheotomy to facilitate weaning, as well as an improvement in survival, both in the ICU and at 90 days.[66,73,74] Burn et al. in a meta-analysis on the use of NIV during weaning reported that NIV can facilitate weaning in mechanically ventilated patients, especially in the subgroup of patients with COPD.[75] Despite a beneficial effect of NIV in hypercapnic respiratory failure, no benefits could be demonstrated from NIV in avoiding reintubation in patients who developed respiratory failure after extubation.[76,77] Because longer time from extubation to reintubation is associated with worse outcome, the delay in reintubation correlates with worse survival rates in patients who received NIV for established post-extubation respiratory failure in these studies.[71,76,77] Subsequently, a strategy based on the early use of NIV during the initial periods after extubation in order to avert respiratory failure after extubation in patients at risk for this complication were explored. Use of NIV following extubation, compared to standard therapy, decreased the reintubation rate and ICU mortality, but not hospital mortality in two randomized trial and this was reemphasized in a recent meta-analysis.[78–80] In conclusion, NIV is definitely useful in facilitating weaning in hypercapnic respiratory failure as well as in the prevention of post-extubation respiratory failure in high-risk patients. Criteria to define patients at high risk for post-extubation respiratory failure are shown in Table 151.3.

Role of Tracheostomy

Tracheostomy is commonly performed to provide long-term airway access in patients who require prolonged mechanical ventilation. The conceptual advantages of tracheostomy includes improved patient comfort, more effective airway suctioning, decreased airway resistance, enhanced patient mobility and more secure airways. These benefits are associated with fewer ventilator complications and accelerated weaning from mechanical ventilation. Thus tracheostomies are more comfortable and impose less breathing work and may decrease the sedation needs.[81] When compared to standard endotracheal tubes, the small radius of curvature of tracheostomy tubes increases turbulent airflow and airway resistance while the short length of tracheostomy tubes reduces overall airway resistance.[82–85] In a randomized trial, early-tracheostomy strategy resulted in lower mortality, fewer cases of pneumonia, fewer accidental extubations and less time spent on a mechanical ventilator in the ICU than a late-tracheostomy strategy.[86] We generally perform tracheostomy in all patients with anticipated ventilatory requirements of more than 7 to 14 days.

TABLE 151.3: Choice of patients to prevent postextubation respiratory failure

1. Elderly patients (age >65 years)
2. More than one consecutive failure of weaning trial
3. Chronic heart failure
4. $PaCO_2$ >45 mm Hg after extubation
5. More than one medical/surgical comorbid illness
6. Poor cough reflex
7. Upper-airways stridor at extubation that does not require immediate reintubation
8. APACHE II score >12 on the day of extubation

Weaning Failure

In patients requiring mechanical ventilation, weaning failure is relatively common, with an estimated prevalence of 31% and a range 26 to 42%.[2,3,6,43] When initial attempts at spontaneous breathing fail to achieve the goal of liberation from mechanical ventilation, clinicians must choose appropriate mode(s) of ventilatory support which maintain a favorable balance between respiratory system capacity and load, attempt to avoid diaphragm muscle atrophy and aid in the weaning process. It is advisable to wait for 24 hours before attempting a new trial of spontaneous breathing. Jubran et al. showed that failures are often due to persistent mechanical alterations in the respiratory system that are unlikely to rapidly reverse.[87] A failed trial can precipitate respiratory muscle fatigue[62] and studies in healthy subjects suggest that complete recovery from fatigue can take longer than 24 hours. In addition, Esteban et al.

showed that multiple daily breathing trials offer no advantage over a once-daily trial.[3] Pressure support or assist-control ventilation modes should be favored in patients failing initial trial/trials. We generally use gradual reduction of PS in these patients with PS reduced by 2 cm H_2O on every six hours.

CONCLUSION

The weaning process is a critical component of ICU care. Both disease factors and management factors may lead to difficult weaning that requires a good assessment for the readiness of weaning. The SBTs in those patients passing the screen is the "gold standard" for ventilator withdrawal assessment should be performed in virtually all patients who are recovering from respiratory failure. Decision to extubate in successful SBT requires further assessments of the patient's ability to protect the airway. In selected patient population especially with hypercapnic respiratory failure, NIV trial to facilitate weaning is warranted.

Extracorporeal Life Support for Severe Acute Respiratory Failure

Steven A Conrad

INTRODUCTION

Acute respiratory failure resulting from Acute Respiratory Distress Syndrome (ARDS) is associated with a mortality rate of 40–50%,[1] and may be even higher at the more severe end of the spectrum. Attempts to maintain gas exchange through the native lungs in this setting often requires application of positive pressure ventilation at levels known to induce lung injury, resulting in Ventilator-Associated Lung Injury (VALI).

Extracorporeal Life Support (ECLS) is a family of extracorporeal cardiopulmonary support techniques, with Extracorporeal Membrane Oxygenation (ECMO) being the most widely applied. During ECMO blood is drained from the central venous system through a vascular cannula, pumped through an artificial membrane lung, and returned to the patient's arterial (venoarterial ECMO) or central venous system (venovenous ECMO). Blood flow through the circuit is high enough to provide full exchange of oxygen and carbon dioxide. Venoarterial (VA) ECMO provides cardiac support by virtue of its provision of Cardiopulmonary Bypass (CPB). Venovenous (VV) ECMO provides no direct cardiac support, but is the support mode of choice in the vast majority of respiratory failure cases.

ECMO is the translation of CPB techniques, used for cardiopulmonary support for several hours during cardiovascular surgical procedures, to prolonged support in the intensive care unit for periods lasting from several days to several weeks. Despite its origin in CPB, ECMO differs from CPB in a number of important ways, including differences in circuit construction, approach to anticoagulation, vascular access, blood flow and temperature management. Although ECMO is used for support of cardiac failure, such as failure to wean from CPB, this chapter will focus on its use in respiratory failure.

Other extracorporeal techniques in common use for respiratory failure include extracorporeal carbon dioxide removal (ECCO$_2$R) and arteriovenous carbon dioxide removal (AVCO$_2$R). ECCO$_2$R is venovenous extracorporeal support utilizing low blood flow (20–25% of cardiac output) for the primary purpose of carbon dioxide removal.[2] This amount of blood flow is sufficient for elimination of carbon dioxide in the management of hypercapnic respiratory failure and as an aid in achieving low tidal volume ventilation. It does not, however, provide sufficient oxygen transfer to support patients with severe hypoxemic respiratory failure, although at higher blood flow partial oxygenation support is achievable. AVCO$_2$R is carbon dioxide removal using a pumpless circuit in which arterial pressure drives blood flow through the oxygenator.[3] This greatly simplifies circuit-reduced resources needed for CO$_2$ removal, but does require cannulation of a peripheral artery, most commonly the femoral artery. In some centers AVCO$_2$R has replaced ECCO$_2$R for the management of hypercapnia.

CLINICAL TRIALS OF EXTRACORPOREAL SUPPORT

Following a report of successful application of VA ECMO in a young adult with post-traumatic ARDS in 1971,[4] VA

ECMO became more widely used in the United States for adult respiratory failure, without standardization of criteria or techniques, and often with little experience on the part of the institution. To address the role of ECMO in the management of severe respiratory failure, a multicenter randomized trial of standard care compared to standard care plus management with VA ECMO was conducted between 1975 and 1978.[5] This trial demonstrated no survival benefit with the use of VA ECMO, with survival approximately 10% in both the control and the ECMO groups. Several factors may have contributed to the observed lack of benefit, including the lack of lung rest (not practiced at that time), high anticoagulation levels and bleeding complications, and the use of venoarterial bypass as opposed to venovenous support.

Gattinoni and colleagues[6] identified the relationship of VALI with poor outcome, and conducted a historical controlled trial of $ECCO_2R$ using low flow venovenous support that suggested a role for this mode of ECLS in acute respiratory failure. Morris et al.[7] sought to duplicate these results with a single center trial of $ECCO_2R$ conducted between 1987 and 1991, in which the ventilator management was directed by a computer-driven protocol. No difference in outcome was found in this trial, but several factors may have contributed to this observed lack of benefit. The $ECCO_2R$ subjects did not receive adequate lung rest, which may have resulted from the enrollment of subjects with severe hypoxemia that could not be oxygenated adequately using lower levels of ventilator support. Bleeding complications were substantial, and large volume transfusions were necessary. This study has often been used as evidence that ECMO does not provide benefit in adult respiratory failure, but this study used $ECCO_2R$, which must be distinguished from ECMO that is capable of providing full oxygen delivery.

A number of clinical and technological advancements in extracorporeal support have been made in the last 20 years that have improved the current practice of extracorporeal support. Recognizing these improvements, Peek and colleagues conducted a national trial of ECMO in the United Kingdom comparing conventional management with conventional management plus ECMO in adults with severe acute respiratory failure (CESAR, Conventional ventilation or ECMO for severe adult respiratory failure).[8] This trial showed that the incorporation of extracorporeal support as part of the management protocol for severe acute respiratory failure resulted in an improved survival without major disability at six months following onset of illness. In addition, the use of extracorporeal support was economical with respect to use of resources.

PRE-ECMO MANAGEMENT

The ECMO is resource intensive and is associated with potential complications; its introduction into the care of a patient should come after conventional measures have failed to provide adequate gas exchange in the setting of lung rest, and in the absence of hemodynamic compromise.

The primary goal of lung protective strategy in mechanical ventilation is to reduce applied mechanical stress to the lungs, with gas exchange a second, albeit important, goal. Ventilator support targets a distending pressure to support oxygenation while minimizing tidal ventilation to reduce the risk of volutrauma. Positive End-Expiratory Pressure (PEEP) should be set above the lower inflection point of a static or slow dynamic compliance curve. In severe ARDS, compliance measurements may not be feasible or interpretable, in which case PEEP in the range of 16–20 cm H_2O can be targeted. Tidal ventilation should be limited to maintain end-inspiratory inflation pressure to less than 30 cm H_2O, and preferably less than 25 cm H_2O. When controlled ventilation is required, pressure control ventilation is preferred over volume ventilation as it provides a larger mean tidal volume for the same end-inspiratory pressure with improved distribution of ventilation. Supported spontaneous ventilation, however, offers several advantages over controlled ventilation, including improved hemodynamic function, minimal to absent sedation requirements, better ventilator synchrony, and preserved cough and ability to clear secretions. With tidal volume determined by the patient and not the ventilator, risk of VALI may be decreased, and this mode can be used as the primary mode of ventilation in ARDS.

Volume overload contributes to impaired gas exchange and higher mortality,[9] and is usually the result of the combination of excessive fluid administration and secondary hypoproteinemia. Careful goal-directed fluid resuscitation with maintenance of plasma colloid oncotic pressure can usually prevent fluid overload. When present, it must be aggressively treated with diuresis or ultrafiltration. Continuous ultrafiltration may be better tolerated.

Prone ventilation improves ventilation-perfusion matching, primarily through improved gas distribution,[10,11] in many patients with severe acute respiratory failure, in particular those with type II ARDS. The resulting improvement in gas exchange and pulmonary mechanics may facilitate the application of lung protective strategies and reduce the need for ECMO. In a randomized trial of prone positioning in ARDS, a subgroup analysis of the quartiles with lowest PaO_2:FiO_2 ratio and highest acute physiology scores.[12]

PATIENT SELECTION

Failure of the above management techniques to achieve adequate unloading of cardiopulmonary support in the setting of potentially reversible pulmonary disease should prompt consideration for ECMO. Selection criteria for initiation of ECMO vary somewhat among ECMO programs, but are generally based on consideration of four components: (1) oxygenation impairment, (2) level of mechanical ventilation support, (3) pulmonary compliance and (4) the extent of pulmonary involvement. Typically patients with a PaO_2/FiO_2 ratio less than 100 (measured on FiO_2 of 1.0), PEEP greater than 15 or mean airway pressure greater than 25, pulmonary compliance less than 20 ml/cm H_2O and bilateral pulmonary involvement will receive extracorporeal support.

The Murray score,[13] which includes all four of these components, has been validated as a marker of severity of ARDS in adults, and was used as one of the main entry criteria in the CESAR trial of adult ECMO.[8] The Murray inclusion score in the CESAR trial was 3 or greater, although the average Murray score of enrolled subjects was higher (3.5) with a PaO_2/FiO_2 ratio of 75, due at least in part to the dependence of enrollment on referrals from outlying institutions. Based on these observations, a Murray score of 3 or greater could be considered a criterion for extracorporeal support.

Other factors may require consideration independent of the above criteria. Severe hypercapnia resulting in respiratory acidosis or requiring high levels of ventilator support, cardiovascular dysfunction secondary to or complicating mechanical ventilator support, and support during procedures with risk of hypoxemia are additional reasons ECMO has been used.

Many centers providing pediatric extracorporeal support have relied on the Oxygenation Index (OI) to guide decisions to provide ECMO. This score considers both the impairment of oxygenation and level of applied support:

$$OI = \frac{FIO_2\ (\%)}{PaO_2} \times MAP$$

A value of approximately 30 and greater is frequently used as a criterion for initiation of extracorporeal support in infants and small children,[14,15] but could also be used in adults.

TECHNIQUES OF ECLS

Extracorporeal Circuit

ECMO employs an extracorporeal circuit that consists of a drainage cannula, a blood reservoir or bladder, a blood pump, an artificial lung (also called an oxygenator), a heat exchanger and return cannula connected by polyethylene tubing (Fig. 152.1). Cannulas are discussed in further detail below:

The bladder is a collapsible chamber that fills with blood draining from the drainage cannula, and provides a reservoir at the inlet to the pump, allowing visual determination of the adequacy of venous drainage. Inadequate drainage can lead to hemolysis and must be avoided. The traditional bladder design is open to the atmosphere, and does not support active suction. It depends on gravity drainage alone, and may require elevation of the patient to achieve adequate venous drainage. A newer bladder design incorporates a rigid housing that can optionally be sealed from the atmosphere, allowing active suction (when required) while serving as a method to monitor inlet pressure and to act as a compliance chamber.

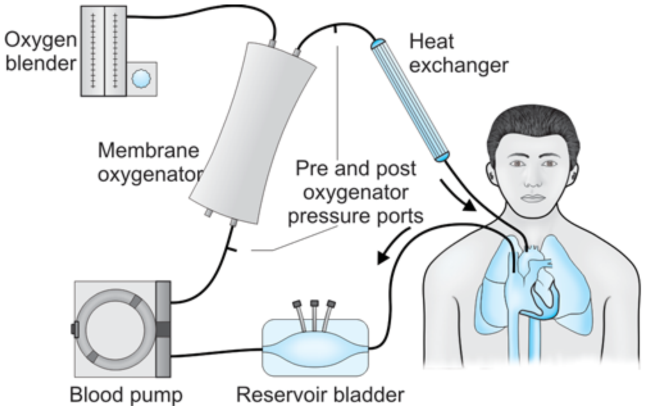

Fig. 152.1: The typical components of an extracorporeal circuit. Vascular cannulas are placed to drain from and return blood to the circulation. Blood drained from the circulation flows into a reservoir (bladder) that serves to maintain blood inflow to the pump. From the pump blood flows through the artificial lung (membrane oxygenator) for gas exchange, then through a heat exchanger to prevent heat loss or control the patient's temperature. Reproduced with permission from Nichols DG, Kochanek PM, Ackerman AD, Singhi SC, Argent AC (Eds). Rogers' Textbook of Pediatric Intensive Care, 4th edition. Lippincott Williams & Wilkins; 2008

The blood pump is capable of pumping up to about 10 l/min, although most patients require 4–5 liters per minute. The two types of pumps available are roller pumps and rotary (centrifugal) pumps. A roller pump is an occlusive pump that employs a rotating head within a fixed housing between which tubing is squeezed as it rotates, forcing blood through the circuit. These have been the mainstay of most ECMO programs for many years, but require continuous monitoring due to the risk of tubing rupture. While older rotary pumps were not well suited for prolonged use, more recent designs have resulted in pumps with desirable features, performance and extended life. A rotary pump uses centrifugal action of a rotating head within a rigid housing to draw blood in under negative pressure into the center, discharging it at the periphery. They are nonocclusive, do not run the risk of circuit tubing rupture, and as a result are rapidly becoming the preferred pump for extracorporeal support.

The artificial lung or oxygenator provides for exchange of oxygen and carbon dioxide between the blood and a gas phase (sweep gas). Artificial lungs are of several types, but only the membrane oxygenator design that prevents contact of the blood and gas phases is suitable for long-term support. The traditional design was that of a flat solid silicone membrane, and could function for days to weeks. The alternative design is the hollow fiber, in which the membrane is tubular in design with a diameter of about 250 micrometers. The sweep gas is delivered inside of the hollow fibers and blood on the outside. Several thousand fibers provide sufficient surface area to support gas exchange in an adult. Although the hollow fiber design is far more efficient than the silicone membrane, the material used in early hollow fiber devices (e.g. microporous polypropylene or PE) was not suitable for long-term support. More recent materials (e.g. polymethylpentene or PMP) have been developed that are suitable for long duration,[16] and are becoming the preferred technology for gas exchange.

The final component of the circuit is the heat exchanger. The high flow rates associated with extracorporeal support, especially in infants and children, can result in loss of heat sufficient to cause hypothermia. The heat exchanger employs circulating water from a temperature control unit to maintain normothermia, or induce mild hypothermia if clinically indicated.

Venovenous ECMO

Venovenous support involves drainage of blood from the central venous system, using the system described above, and returning back into the central venous system (Fig. 152.2). This approach provides only support of gas exchange, as the patient's cardiac output is provided by the cardiovascular system. Since blood is returned into the same vascular bed from which it is withdrawn, leading to recirculation and incomplete mixing, venous blood entering the right heart is never fully saturated with oxygen. Oxygen saturation values on VV ECMO typically run 80–85%, but can be as low as 75%. With the newer dual lumen cannulas that reduce recirculation, values of 85–90% or even higher may be seen. Although diminished, these values are able to provide adequate oxygen delivery if cardiac output is maintained and hemoglobin levels are in the normal range (14–15 gm/dl). The use of inotropic and/or vasopressor agents in low doses is often required, but dose requirements are usually much lower once ventilator support is reduced following ECMO initiation. Transfusion is usually required to attain the target hemoglobin. Mixed venous oxygen saturation values are not attainable, so, metabolic monitoring with

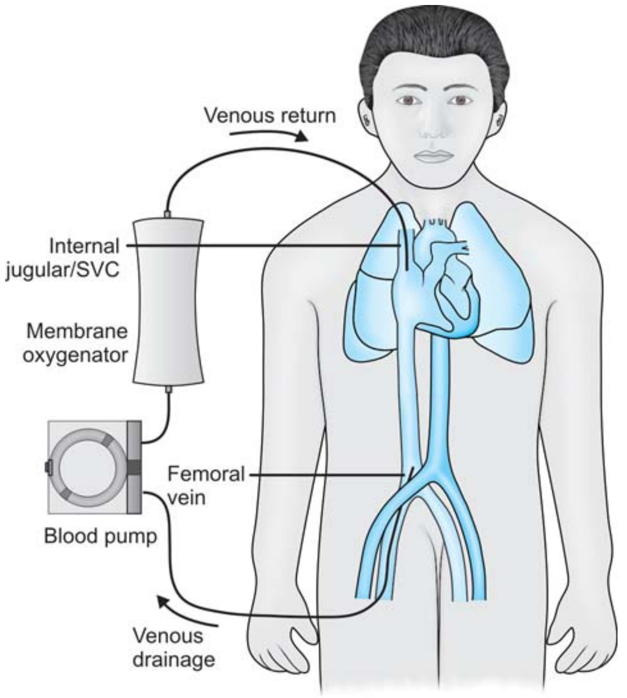

Fig. 152.2: Typical circuit configuration for VV ECMO, in which blood is withdrawn from the central venous system through the internal jugular vein, pumped through the circuit (simplified for this figure), then returned to the venous system through the femoral vein. Reproduced with permission from Nichols DG, Kochanek PM, Ackerman AD, Singhi SC, Argent AC (Eds). Rogers' Textbook of Pediatric Intensive Care, 4th edition. Lippincott Williams & Wilkins; 2008

lactate helps to identify inadequate oxygen delivery. Blood flows in the range of 75–100 ml/kg/min are typical for VV ECMO.

During VV ECMO, oxygen delivery is highly dependent on blood flow, so, achieving an adequate extracorporeal blood flow is necessary. Carbon dioxide removal, on the other hand, is more dependent on the amount of sweep gas delivered to the artificial lung. Typical sweep gas values during VV ECMO range from about 100–150% of blood flow, and lower as native lung function returns.

Venoarterial ECMO

VA ECMO involves drainage of blood from the central venous system and returning it to the arterial system, bypassing the heart and lungs as is done in cardiopulmonary bypass for cardiac surgical procedures (Fig. 152.3). The ECMO circuit contributes to both gas exchange and cardiac output, thus useful for patients with severe reversible cardiac failure. Oxygen saturation values on VA ECMO are high (95% or higher) since there is no admixture with venous blood. Mixed venous oxygen saturation can be monitored to direct the amount of ECMO flow required, and blood flow is set to target a normal SvO_2. Inotropic and vasopressor agents can usually be weaned to low levels or discontinued.

A potential complication of VA ECMO when native Left Ventricular (LV) function is severely impaired is LV dilatation. The added afterload from blood delivery into the arterial system combined with incomplete drainage of right atrial blood may result in LV distention that can impair myocardial oxygen delivery and ventricular recovery. Another complication that can occur when native LV function is somewhat preserved is inadequate oxygen delivery to the coronary vessels. If ventricular ejection during VA ECMO is sufficient to keep the extracorporeal blood from reaching the coronary ostia, then the blood perfusing the myocardium will be deoxygenated blood from the pulmonary system. If a patient is placed on VA ECMO but recovers sufficient ventricular function, consideration should be given to converting the extracorporeal flow from VA to VV.

Venovenous Carbon Dioxide Removal

Patients with severe hypercapnic respiratory failure or those with severe hypoxemic respiratory failure who develop severe hypercapnia as a result of protective ventilator strategies, but otherwise adequate oxygenation may be considered for $ECCO_2R$. $ECCO_2R$ is essentially identical to VV ECMO but with the placement of smaller cannulas and reducing blood flow to 1–1.5 l/min.[6] This blood flow is adequate for complete CO_2 removal since the artificial lung transfers carbon dioxide 20 times more efficiently that it does oxygen, and the CO_2 dissociation curve is nearly linear (unlike the oxygen dissociation curve).

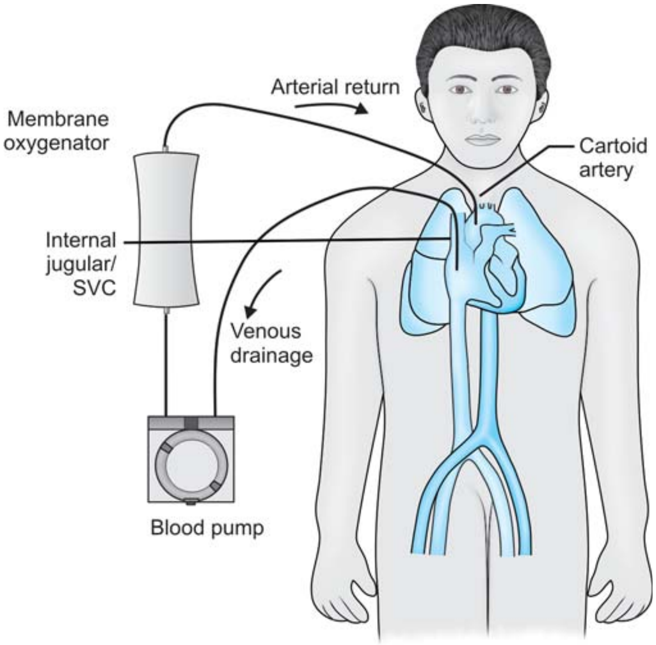

Fig. 152.3: Typical circuit configuration for VA ECMO, in which blood is withdrawn from the central venous system through the internal jugular vein, pumped through the circuit (simplified for this figure), then returned to the aorta through the internal carotid artery. Reproduced with permission from Nichols DG, Kochanek PM, Ackerman AD, Singhi SC, Argent AC (Eds). Rogers' Textbook of Pediatric Intensive Care, 4th edition. Lippincott Williams & Wilkins; 2008

Arteriovenous Carbon Dioxide Removal

Since carbon dioxide removal can be achieved with low blood flows, an alternative to $ECCO_2R$ is pumpless $AVCO_2R$.[3] This simplified circuit uses an artificial lung connected directly to arterial and venous cannulae without a blood pump, relying on the patient's arterial blood pressure to drive blood flow. Using an arterial cannula of 12 Fr and a venous cannula of 16 Fr, blood flows of 600–800 ml/min can be achieved at normal blood pressures, sufficient for total carbon dioxide removal.[17] Cannulation is performed on the femoral vessels, and support for up to several days can be achieved including in pediatric patients.[18]

VASCULAR CANNULATION

Perhaps the most challenging aspect of the application of ECMO is gaining access to the vascular system to support the blood flow required for extracorporeal support.

VV ECMO for respiratory support does not contribute to cardiac output, and the amount of blood flow required depends not on existing cardiac function, but on existing pulmonary function. If native pulmonary gas exchange is absent, the extracorporeal circuit must be able to oxygenate most of the venous return, requiring extracorporeal blood flow approaching that of the native cardiac output. Since an arterial oxygen saturation of 75% or more in the face of preserved cardiac output usually results in adequate systemic oxygen delivery, extracorporeal blood flow can be less than cardiac output.

In VA ECMO, extracorporeal flow depends on the existing native cardiac output. Since extracorporeal blood flow in VA ECMO contributes directly to the cardiac output, it can be as high as the needed cardiac output if native cardiac function is minimal. When native cardiac output is not depressed, blood flow in VA ECMO will be correspondingly less than the required cardiac output.

Cannulas for Venovenous Support

The availability of dual lumen, dual drainage port catheters permit the use of a single cannula to provide full venovenous support. This cannula is placed into the right internal jugular vein, extending across the right atrium and into the inferior vena cava. Its design includes a drainage lumen with two drainage ports that withdraw blood from the superior and inferior vena cava, respectively, and a return lumen with a discharge port that lies in the right atrium directed at the tricuspid valve. The cannula is available in sizes appropriate for neonatal use (12 and 13 Fr) up to adult use (27 and 31 Fr), with a range of sizes in between. The adult cannulas provide typical blood flow of 4–5 liters per minute, adequate for full support of essentially any adult.

An alternative to use of a dual lumen cannula is the placement of two or three single lumen cannulas, as has been the practice prior to availability of dual lumen cannulas. Although the dual lumen cannula has largely replaced the use of multiple single lumen cannulas, the latter technique is capable of providing higher blood flows in those few patients that may require it. With two cannulas, drainage is achieved through a right internal jugular cannula inserted to the superior cavoatrial junction, and return is achieved through a femoral venous cannula inserted to the depth of the iliac vein.

The two-cannula approach is associated with a variable degree of recirculation. Recirculation occurs when oxygenated blood returned to the patient in the inferior vena cava is aspirated by the drainage cannula rather than flowing into the right ventricle (RV), reducing effective oxygen transport only to that fraction not undergoing recirculation. Recirculation is inevitable in this approach since the blood flow in the ECMO circuit is typically greater than the blood returned via the superior vena cava. Paradoxically, attempts to raise overall blood flow can increase the recirculation fraction, worsening oxygenation.

The use of three cannulas can decrease recirculation by mimicking the blood flow pattern of the single lumen cannula.[19] Two short drainage cannulas are placed in the superior vena cava and iliac veins through the right internal jugular and a femoral vein, and a long return cannula is placed in the contralateral femoral vein to the level of the hepatic veins. Since each drainage cannula flows approximately half of the extracorporeal blood flow, each cannula is less likely to exceed the flow in its respective vein, reducing recirculation.

Cannulas for Venoarterial Support

Venoarterial support requires the placement of two single lumen cannulas. The venous drainage cannula is usually placed in the right internal jugular (23–24 Fr) and the arterial cannula is placed in the right common carotid (16–19 Fr) by surgical cutdown. This allows a single incision for both cannulas, and provides arterial return to the ascending aorta to provide blood to the myocardium and cerebral vessels.

Partial venoarterial support by the femoral route can be performed by percutaneous insertion with a 23–24 Fr femoral venous cannula and a 16 Fr femoral arterial cannula. Since this does not provide oxygenated blood to the upper body, it should be used when pulmonary function is adequate to oxygenate blood, or as a component of hybrid venovenoarterial (VVA) support.

Cannulation Technique

Venovenous cannulas for respiratory support can be placed percutaneously with the Seldinger technique as are smaller vascular catheters for monitoring purposes. The selected vein is accessed with a needle and guidewire, a skin incision is made, and the tract dilated in 4 Fr increments to the approximate size of the cannula. The cannula is then placed over a loading dilator and inserted over the guidewire into the vein. When the internal jugular site is accessed, the patient should have neuromuscular blockade to prevent air embolism, since even small respiratory efforts can result in a large volume of air entry. The use of ultrasound prior to cannulation enables the selection of a vein of adequate size to hold the cannula, and its use during cannulation helps ensure appropriate intraluminal placement. Fluoroscopy or transesophageal echocardiography is recommended during placement of dual lumen cannulas, as the distal end of the catheter can enter the RV instead of the inferior vena cava, increasing the risk for complications.

Cannulation for full venoarterial support for cardiac failure is typically performed by surgical cutdown in the neck with open cannulation of the right internal jugular vein and common carotid artery. In this approach, the cannula size can be chosen at the time of insertion, and the vein and artery are ligated following cannula placement. When partial venoarterial support is required and pulmonary gas transfer is adequate, percutaneous femoral vessel cannulation can be considered. The cannula size is smaller to avoid complete luminal obstruction leading to limb ischemia. During partial support using the femoral vessels, oxygenated blood from the ECMO circuit does not reach the brain and myocardium, thus native lung function must be adequate to oxygenate the pulmonary blood. If pulmonary function is not adequate, an alternative is to use hybrid VVA support that combines partial venoarterial femoral bypass with traditional venovenous support for oxygenation failure.

MANAGEMENT DURING SUPPORT

Following institution of extracorporeal support, patient management focuses on application of lung rest, limitation of sedation, optimization of cardiovascular function and organ perfusion, correction of fluid overload, modulation of pulmonary and systemic inflammation, anticoagulation and introduction of nutritional support. ECMO provides support of gas exchange but does not treat the underlying disorder. The benefits of ECMO appear to come from reduced mechanical stress applied to the lungs, improvement in myocardial oxygenation and function, and improved organ perfusion with reduced dependence on cardiovascular pharmacologic support.

Mechanical Ventilation

Reduction in the level of support provided during mechanical ventilation is associated with reduced mechanical stress, reduced pulmonary inflammation and improvement in outcome.[20,21] Lung rest during ECMO consists of the application of a modest level of PEEP, e.g. 10 cm H_2O, limitation of tidal volume to maintain plateau pressures at or less than about 20 cm H_2O, and reduction in respiratory rate to less than 10/minute. There is no evidence that maintaining an “open lung” approach during ECMO is necessary for lung recovery. Since gas exchange no longer has to be provided by the lungs, very minimal ventilator settings can be achieved and are well tolerated.

Spontaneous supported ventilation has numerous advantages over controlled ventilation, including improved ventilator synchrony, improved hemodynamics, avoidance of neuromuscular blockade, reduction in sedation requirements and enhanced patient interaction. Since the patient on supported ventilation has control over the respiratory pattern, she can adapt to altered lung mechanics that minimizes the risk of pulmonary injury. In addition, patients on supported ventilation and lowered sedation levels can provide an effective cough to help maintain clearance of bronchial secretions. When using spontaneous ventilation, intrathoracic pressures are further lowered as compared with controlled ventilation even when inflation pressures provided by the ventilator are comparable. This strategy has resulted in higher survival in one small series of patients.[22]

VV ECMO provides improved oxygenation to the prepulmonary circulation, reducing effective right-to-left shunt and improving myocardial oxygen delivery. Simultaneously, RV afterload is reduced as a result of reduced intrathoracic pressures, thus improving myocardial oxygen delivery and reducing oxygen requirements of the ventricle. The resulting improved myocardial function allows reduction in pharmacologic inotropic support of ventricular function. Vasopressors can be discontinued or their dose reduced in the majority of patients. Organ perfusion is usually improved, and urine output often increases.

Anticoagulation

The extracorporeal circuit is a large surface capable of contact activation of blood coagulation, so anticoagulation is required in all patients except for brief periods of time. The greatest experience is with unfractionated intravenous heparin. Because of the low cost and the ability for point-of-care testing, heparin remains the drug of choice in the vast majority of ECMO centers. Monitoring is performed with the bedside Activated Coagulation Time (ACT) or the Activated Partial Thromboplastin Time (aPTT). The ACT is a whole blood test, which is influenced by factors in addition to heparin such as fibrin degradation products. Although a crude measurement, its utility is great since it looks at overall coagulation including platelet function, and can be obtained on a frequent basis if needed. The normal ACT is on the order of 120 seconds, and the usual therapeutic range is 180–200 seconds. This range can be reduced to 160–180 seconds (or lower) to help manage bleeding complications for extended periods of time, although with an increased risk of clot development in the circuit. The aPTT is a test of plasma clotting factors and correlates better with heparin levels than the ACT, but may not give any indication of nonheparin factors contributing to anticoagulation. Therapeutic levels are on the order of 60–80 seconds. Some centers monitor both, with ACT levels monitored more frequently and aPTT monitored at less frequent intervals. Another test that may prove useful when trying to evaluate bleeding problems on ECMO is the Thromboelastogram (TEG), a whole blood test that provides more insight into the various components of clotting function.

Fluid Management

Patients with severe pulmonary dysfunction may require ECMO prior to optimization of clinical status (such as elimination of fluid overload) as a result of life-threatening hypoxemia. Fluid overload may thus be present and will require diuresis or ultrafiltration. Since continuous renal replacement therapy equipment (or even a simple hemofilter) is easily placed into the ECMO circuit, this modality is commonly used for the correction of fluid overload on ECMO even in the absence of acute kidney injury. Anticoagulation levels required for management of the ECMO circuit are sufficient to maintain hemofilter patency.

Other Management

Many ECMO centers administer corticosteroids throughout the ECMO course in the setting of ARDS (e.g. methylprednisolone 1–2 mg/kg/day), which have been demonstrated to improve outcomes.[23] Patients on spontaneous supported ventilation will usually clear secretions adequately, but patients requiring full sedation and controlled ventilation may benefit from bronchoscopy to assist with secretion management. Prophylaxis against infection is achieved by frequent (every 24–48 hours) skin preparation of the cannulation sites using 4% chlorhexidine. Selective decontamination of the gastrointestinal tract is employed to help reduce risk of nosocomial infections and multiple organ dysfunction.[24,25] Nutritional support is provided via the enteral route,[26] with parenteral nutrition avoided unless absolutely necessary.

TRANSITIONING FROM ECMO

Following initiation, extracorporeal support is continued until pulmonary recovery is adequate to support gas exchange with minimal ventilator settings (e.g. pressure support ventilation with FiO_2 of 0.4 or less). Time to recovery varies considerably, averaging 1–2 weeks, but can be much longer, with pulmonary recovery and survival reported after 3–4 months of support. Pulmonary fibrosis on biopsy, once considered irreversible and a reason to discontinue ECMO, has the potential to improve. As a result, most centers will provide prolonged support in anticipation of recovery.

Recovery of pulmonary function is heralded by improvement in oxygenation independent of changes in ECMO support, improvement in lung compliance manifested by increasing tidal volume to normal with modest pressure support, and clearing of radiographic densities. It is tempting to reduce the level of ECMO support once recovery begins, but loading of the pulmonary system is not recommended until pulmonary recovery is well established. With VV ECMO, a discontinuation of sweep gas alone is sufficient to eliminate support and can be performed intermittently to assess the patient's ability to maintain gas exchange on mechanical ventilation alone. With VA ECMO, elimination of sweep gas alone should not be performed since it amounts to a large right-to-left shunt. A reduction in blood flow to minimal levels and shunting blood flow through an external bridge in the circuit are the two ways to assess the response to discontinuation of support.

Once the patient can sustain gas exchange and hemodynamics with minimal to absent extracorporeal support, the cannulas are removed. Percutaneously placed venous cannulas are removed and a suture is placed in the subcutaneous tract to prevent bleeding. Percutaneously placed arterial cannulas are removed and managed with prolonged pressure, an occlusion device, or surgical repair depending on the size and location of the cannula. Surgically placed arterial and venous cannulas are removed by surgical means.

A major reason for nonrecovery and death or discontinuation of support is the development of progressive pulmonary hypertension and RV failure. Pulmonary artery pressures approach systemic levels and RV dilatation is noted on echocardiography. This usually represents an irreversible condition. Development of this during VV ECMO has been a reason to switch to VA ECMO, but survival is uncommon.

SUMMARY

Technological improvements such as percutaneous cannulation technique, dual lumen cannulas, high efficiency long duration artificial lungs and efficient blood pumps have made the application of extracorporeal support much safer with a lower risk of mechanical complications. With data from a recent clinical trial supporting the addition of ECMO to the management of severe acute respiratory failure, ECMO is moving into the mainstream of support of these patients.

Hyperbaric Oxygen Therapy*

PS Tampi, SK Jindal

INTRODUCTION

Hyperbaric Oxygen Therapy (HBO_2T) is the administration of oxygen at a pressure greater than that at sea level, which is one atmosphere. Hyperbaric medicine owes its origin to the problems encountered by deep-sea divers, exposed to high pressure diving sports, commercial or military expeditions at depths of 10 m or more. In clinical medicine, this is simulated by exposing a patient to hyperbaric atmosphere in a closed monoplace or multiplace chamber. In either case, the partial pressure of oxygen (PaO_2) will approach 1500 mm Hg at a pressure equivalent to 33 feet of seawater. A century of research in oxygen administration has established that the effects are dose related, and the hyperbaric environment merely provides the opportunity to give higher doses than can be achieved at sea level.

HISTORY OF HYPERBARIC MEDICINE

Development of Hyperbaric Air Therapy

The British physician Henshaw used compressed air for medical purposes in 1662 in an airtight room called a "domicilium" in which variable climatic and pressure conditions could be produced, with pressure provided by a large pair of bellows. According to Henshaw, "In times of good health, this domicilium is proposed as a good expedient to help digestion, to promote insensible respiration, to facilitate breathing and expectoration, and consequently, of excellent use for the prevention of most afflictions of the lungs." There is however, no account of any application of Henshaw's proposed treatment, and there were no further developments in the field of hyperbaric therapy for nearly two centuries.

In the nineteenth century, there was a rebirth of interest in hyperbaric therapy, in France. In 1834, Junod built a hyperbaric chamber to treat pulmonary afflictions using pressures of two to four Absolute Atmospheres (ATA). In 1837, Pravaz built the largest hyperbaric chamber of that time, and treated patients with a variety of ailments. Fontaine, in 1877, developed the first mobile hyperbaric operating theater, and by this time hyperbaric chambers were available in all major European cities. Interestingly, there was no general rationale for hyperbaric treatments, and prescriptions therefore, varied from one physician to another. During the second half of the nineteenth century, hyperbaric centers were advertised as being comparable to health spas. Junod referred to his treatment as "Le Bain d'air comprimd" (the compressed-air bath). In 1855, Bertin wrote a book on this topic and constructed his own hyperbaric chamber.

The first hyperbaric chamber on the North American continent was constructed in 1860 in Oshawa, Ontario, Canada, and east of Toronto. It was later shifted to New York, to treat nervous disorders. The chamber that was built by Cunningham received the most publicity, and was the most actively used in Kansas City in the 1920s. Cunningham claimed to have achieved remarkable improvement in patients who were cyanotic and comatose. Cunningham reasoned that a barometric factor was therefore involved. However, one night a mechanical failure resulted in a complete loss of compression and all his patients died. This tragedy was a sobering lesson but ultimately did not deter Dr Cunningham. His enthusiasm for hyperbaric air continued, and he started to treat diseases such as syphilis, hypertension, diabetes mellitus and cancer. Its reasoning was based on the assumption that anaerobic infections played a role in the etiology of all such diseases. In 1928, Cunningham constructed the largest chamber ever built (five stories high and 64 feet in diameter), in Cleveland. Each floor had one bedroom with all the amenities of a good hotel. At that time, it was the only functioning hyperbaric chamber in the world. The Cunningham chamber was dismantled for scrap in 1937, which brought to a temporary end of the era of hyperbaric air therapy for medical disorders.

Development of Hyperbaric Oxygen Therapy

Oxygen was not "discovered" until 1775, when the english scientist Joseph Priestley isolated what he called "dephlogisticated air" (Chapter 1). Although, hyperbaric air had been used as early as 1662, oxygen was not specifically added to early hyperbaric chambers. The toxic effects of concentrated oxygen reported by Lavoisier and Segiom in 1789 were reasons enough for hesitation to use it under pressure. Paul Bert, the father of pressure physiology, discovered the scientific basis of oxygen toxicity in 1878. The potential benefits of using oxygen under pressure for the treatment of decompression sickness were first realized by Drager, who in 1917 devised a system for treating diving accidents. It was not until 1937: The very year that Cunningham's "air chamber" hotel was demolished, that Behnke and Shaw actually used hyperbaric oxygen (HBO_2) signifying the arrival of the era of HBO_2 therapy.

Rationale of Hyperbaric Oxygen

An increased atmospheric pressure increases the partial pressure of O_2 in the alveolar air and arterial blood, provided the fractional concentrations of oxygen remains the same. This is easily derived from the alveolar air equation. Since the oxygen dissolved in the plasma depends upon PaO_2, the dissolved O_2 content of blood is also increased. This is independent of Hb levels of the blood. Therefore, under hyperbaric conditions the total oxygen carrying capacity of the blood is significantly more (Table 153.1). At 1 atmosphere (sea level), with a person breathing 100% O_2, the PaO_2 is about 670 mm Hg and the total oxygen content of 18.7 ml/dl. Increasing the pressure to 3 atmospheres, the PaO_2 increases to about 1700 to 1800 mm Hg and the total O_2 content to 22 ml/dl. Of this, about 25% (i.e. 5.5 ml/dl) is dissolved in plasma. This in fact is equivalent to the total oxygen content of blood under normal conditions, at much lower Hb level of 4 gm%. Therefore, under hyperbaric conditions, it is possible to maintain adequate oxygen content of blood as well as delivery to the tissues with a very low or no hemoglobin at all. However, it should be remembered that the whole of the tissue oxygen requirements can be met by dissolved oxygen, only if PaO_2 is around 2025 mm Hg.

TABLE 153.1: Shows the different components of oxygen content of the blood at different atmospheric pressures at constant plasma hemoglobin of 14 gms/dl, when breathing 100% O_2

Pressure	*PaO_2 (mm Hg)*	*Dissolved O_2 (%)*	*Total O_2 content (atmospheres) (ml/dl)*
1	670	11	18.7
2	1200-1300	18	20
3	1700-1800	25	22

Other Physiological Effects of Hyperbaric Oxygenation

Effect on $PaCO_2$: An increased hemoglobin saturation of venous blood reduces its ability to carry CO_2, and results in carbon dioxide accumulation (Haldane effect).
Vasoconstriction: Occurs due to increase in PaO_2, and has a therapeutic value.
Angiogenesis: The mechanism by which this occurs is not known but occurs only when oxygen is administered at more than 1 ATA, and does not occur with 100% oxygen at 1 ATA.

Beneficial Effects of HBO

Hyperbaric oxygen administration achieves two principal objectives:

1. It increases PaO_2 and tissue PO_2 to levels higher than those obtained at 1 atmosphere. This has several potential therapeutic benefits. The oxygen delivery to the tissues is increased, which may promote healing; the phagocytosis and antibiotic action on the microorganisms are augmented. Hyperoxia induces vasoconstriction, which reduces tissue edema. Finally, the oxygen dissolved in the plasma is available to the tissues, without any increase required in the hemoglobin level. This is not associated with any increase by blood transfusions. Problems of increased blood viscosity are therefore, avoided.
2. There is an increase in the ambient pressure which increases interstitial tissue pressures as well. This is

used to treat decompression sickness, which may occur in divers. Similarly, presence of air or gas in the blood either injected accidentally during some procedure or due to embolization can be absorbed with HBO_2 therapy.

Mechanism of Action of HBO_2

i. HBO_2 increases dissolved oxygen in the plasma, which readily diffuses into the hypoxic tissues.
ii. Increased oxygenation results in vasoconstriction at the site, resulting in induced transudation, reduction in capillary pressure, and thereby reducing the tissue edema.
iii. The reduction in tissue edema reduces compression of the cells, thereby enhancing the reabsorption of fluid.
iv. With edema being less, barriers of diffusion are reduced and oxygen diffusion to the tissues improves, resulting of improvement in tissue functions.
v. Improved vascularization due to neovascularization results in speedy recovery of tissues and gives way to tissue regeneration.
vi. Oxide, hydro-peroxide and superoxide radicals of oxygen are toxic, and interfere with cell metabolism of bacteria, and thereby destroy the bacteria.
vii. HBO_2 modulates the immune system and helps in the faster elimination of viruses.
viii. Bacterial killing effect of leukocytes is impaired in the hypoxic state. Increased oxygenation will enhance the killing power of leukocytes.

INDICATIONS

Enthusiasm with the use of HBO_2 now is almost similar to what was seen with use of normobaric oxygen in the 19th century, when its therapeutic applications were first discovered. But this enthusiasm has helped to discover its beneficial role as an adjunct in the treatment of diverse clinical conditions. Indications may vary in different countries in different settings. Some of the more definite indications are the decompression sickness, air embolism, gas gangrene, and carbon monoxide poisoning. The indications apprised by the Undersea and Hyperbaric Medical Society are rather limited and rely on the proof of efficacy of controlled studies.

Decompression Sickness

Decompression sickness occurs, when the ambient air pressure is allowed to lower rapidly after a prolonged exposure to a higher pressure. This is commonly seen in the deep sea divers, after emerging from a diving juggernaut, and occasionally in the aviators or astronauts on reaching the outer atmosphere or space. Due to a sudden lowering of pressure, the inert gases dissolved in body fluids bubble out in both intravascular and extravascular compartments resulting in multiple symptoms. The common clinical manifestations include musculo-skeletal pains, neurological symptoms such as paresthesias and sensori motor deficits, nausea, vomiting, nystagmus, tinnitus, sub-sternal pain, cough, dyspnea, hoarseness of voice, and occasionally shock and death.

Hyperbaric oxygen and recompression to about 60 feet constitute the mainstay of therapy. Both steps help in the reduction and resolution of the bubbles and maintenance of tissue oxygenation. Increased occurrence of oxygen toxicity under higher pressure conditions limits the duration of use of hyperbaric oxygen. Relapse may occur after discontinuation, of therapy. Short-term observation, especially in patients with neurological symptoms for at least six hours is generally recommended. Some people advocate the provision of observation units for about 24 hours after hyperbaric therapy.

Air Embolism

Air bubbles may form in the venous circulation, due to sudden decompression (e.g. decompression sickness) or more commonly get introduced during central venous instrumentation, invasive medical and surgical procedures, hemodialysis, chest trauma or positive pressure ventilation, employing high levels of Positive End Expiratory Pressures (PEEP). These air bubbles finally end up in the lungs, causing obstruction of pulmonary circulation, and presenting a picture of pulmonary air embolism. It may occasionally be fatal if a large pulmonary vessel gets blocked. Bubbles may also form in the arterial circulation, but are rare because of the higher hydrostatic pressure in the larger vessels. Cerebral air embolism is uncommon but more serious in nature.

Treatment of air embolism employs resuscitative and restorative measures for pulmonary circulation through removal and/or absorption of air from the pulmonary vessels. Attempts to remove the air bubbles include the direct needle aspiration, Trendelenburg position or removal through a central venous catheter. Administration of 100% oxygen helps reabsorption of air. Hyperbaric oxygen administration rapidly reduces the bubble size. Generally 50% O_2 at a pressure of 165 feet is administered initially for a few minutes followed by intermittent periods of 100% oxygen at a lower pressure of 65 feet. A recent report on the use of U.S. Navy Treatment suggests this use of oxygen filled monoplace hyperbaric chamber as better tolerated, and safer from oxygen toxicity point of view than a multiplace chamber, for the treatment of both decompression sickness and air embolism.

Gas Gangrene and Other Necrotizing Infections

There is an increased evidence to suggest a major role of HBO_2 on inflammatory cytokines and mediators. It is shown to cause cytokine down-regulation and growth factor up-regulation. HBO_2, therefore is likely to promote wound healing by suppressing inflammation and facilitating repair. It also augments the antibacterial action of leukocytes, which gets otherwise inhibited under hypoxic conditions and thereby improves the efficacy of antibiotics. These effects have been shown in a few clinical trials and clinical experience, when used as an adjunct treatment for gas gangrene, non-healing wounds (e.g. diabetic foot), osteomyelitis and necrotizing fasciitis. It is also shown to shorten the treatment with antibiotics for soft tissue infections.

Hyperoxygenation in particular is valuable in gas gangrene, since it inhibits the growth of the causative anerobic microorganisms, i.e. clostridia and prevents formation of toxins responsible for necrotizing myositis and myonecrosis. Reports on the useful role of HBO_2 are available for treatment of all kinds of clostrial infections including necrotizing fasciitis of upper extremities, orbital gas gangrene, recurrent crepitant cellulitis with extensive subcutaneous emphysema. It has been also used in patients with refractory mycoses, leprosy, and other intractable infections.

Carbon Monoxide Poisoning

Carbon monoxide (CO), a byproduct of incomplete combustion of coal, is a poisonous gas. It is a common cause of death in miners and other personnel working with coal furnaces in foundaries and factories. CO poisoning in India, occurs in people burning indoor coal for heating and cooking during winter months in ill ventilated houses. Deaths in this scenario are commonly reported in individuals sleeping in closed rooms. Malfunctioning air conditioning systems in cabins have been occasionally blamed for CO poisoning.

CO poisoning is generally insidious. Neurological complications are most frequent. Some of the common symptoms include headache, confusion, dizziness, nausea, and vomiting. In more serious forms, syncope, seizures and coma may precede death. Cardiac arrhythmias and pulmonary edema may also occur.

CO has an affinity for hemoglobin, almost 300 times that of oxygen. Exposure to CO therefore quickly results in displacement of oxygen and formation of carboxy hemoglobin (HbCO).

Treatment of CO poisoning needs to be prompt and aggressive. A great degree of evidence supports that hypoxia occurs late in CO poisoning. But the treatment of both, the actually poisoned persons as well as the environmental exposures, are based on a hypoxic theory of toxicity. Oxygen therapy is the mainstay of therapy besides other supportive care. Oxygen accelerates the dissociation of CO from hemoglobin and other heme proteins. Oxygen with an FiO2 of 100% is administered with a high flow and the response is quick, provided the treatment is started in time before any organ damage has occurred.

Hyperbaric oxygen has been used in a few trials. It rapidly decreases blood HbCO. It may also delay the occurrence of delayed brain injury. But there is no conclusive evidence to support its use. Firm guidelines regarding the use of hyperbaric oxygen cannot be established from the available literature.

Adjunct to Treatment of Cancers

HBO_2 may improve the treatment of malignant tumors by increasing the tumor sensitization to radiotherapy. A significant improvement is reported with HBO_2 followed by radiotherapy for local tumor control, mortality for cancers of the head and neck, and local tumor recurrences in cancers of head, neck and uterine cavity. It also improves the response to photodynamic and chemotherapy, possibly by raising intra-tumoral oxygen tension. It was also shown to improve survival in locally advanced breast cancer undergoing neoadjuvant chemotherapy. It may also promote new vessel growth into areas with reduced oxygen tension, thereby promoting healing of radiation induced tissue injury.

Miscellaneous Conditions

- *Plastic and reconstructive surgery:* For non-healing wounds, including radiation wounds and venous leg ulcers, as an aid to the survival of skin flaps with marginal circulation, as an aid to re-implantation surgery, as an adjunct to the treatment of burns
- *Trauma:* Crush injury, compartment syndrome, soft tissue sports injuries

- *Orthopedics:* Non-union of fractures, bone grafts, osteoradionecrosis
- *Peripheral vascular diseases:* Shock, myocardial ischemia, aid to cardiac surgery
- *Neurological:* Stroke, multiple sclerosis, migraine, cerebral edema, multi-infarct dementia, spinal cord injury and vascular diseases of the spinal cord, brain abscess, peripheral neuropathy, radiation myelitis, vegetative coma
- Chronic pain from fibromyalgia syndrome, myofascial pain syndrome, migraine and cluster headache
- *Hematology:* Sickle cell crises, severe blood loss anemia
- *Ophthalmology:* Occlusion of central artery of retina
- *Gastrointestinal:* Gastric ulcer, necrotizing enterocolitis, and paralytic ileus, pneumatoides, cystoides intestinalis, hepatitis
- *Otorhinolaryngology:* Sudden deafness, acute acoustic trauma, labyrinthitis, Meniere's disease, malignant otitis externa (chronic infection)
- *Lung diseases:* Lung abscess, pulmonary embolism (adjunct to surgery)
- *Endocrines:* Diabetes
- *Obstetrics:* Complicated pregnancy, diabetes, eclampsia, heart disease, placental hypoxia, fetal hypoxia, congenital heart disease of the neonate
- *Asphyxiation:* Drowning, near hanging, smoke inhalation
- *Aid to rehabilitation:* Spastic hemiplegia of stroke, paraplegia, chronic myocardial insufficiency, peripheral vascular disease.

CONTRAINDICATIONS

Contraindications for HBO_2 therapy can be divided into the absolute contraindication, which include untreated tension pneumothorax; and relative contraindication, which includes upper respiratory infections, emphysema with CO_2 retention, symptomatic pulmonary lesions seen on chest X-ray, history of thoracic or ear surgery, uncontrolled high fever, pregnancy, claustrophobia, seizure disorders, and malignant diseases.

COMPLICATIONS

The complications in the use of HBO_2 are related to pressure changes and the toxic effects of oxygen. They include baro-trauma to ear, sinuses, or lungs. Trauma to ears or sinuses may be averted with slow compression, the use of decongestants, patient education and rarely myringotomy. Pulmonary baro-trauma is very rare, perhaps occurring 1 in 50,000 treatments. It can be prevented by careful pre-treatment screening for pulmonary blebs, air trapping caused by bronchospasm or secretions, pre-existing pneumothorax, central lines and ventilatory support. Oxygen toxicity with occurrence of grand-mal seizures are noticed beyond a depth of 3 ATA (66 feet or 20 m of seawater). Damage of lung tissue, manifested by decrement in vital capacity and irritation to large airways may occur due to oxygen toxicity following HBO_2. Increased pressure causes increased gas density and airway resistance. This produces an altered voice called the "Donald Duck voice", and an increased awareness of breathing. Hypoventilation may result especially in a patient with the underlying obstructive lung disease. Increased partial pressure of nitrogen causes symptoms of mild euphoria at pressure of 2.5 atmospheres, progressing to frank intoxication, and decreased performance at over 4 atmospheres. Accumulation of O_2 may occur in the event of an exposure for several days. Hyperpnea and occasionally respiratory acidosis may result. Other toxic substances or pollutants, which may continue to accumulate in a closed chamber and reach toxic pressures, include alcohol (from disinfectant solution), sulphur dioxide, hydrocarbons, carbon monoxide, volatile substances and mercury vapors. A regular monitoring is required for their concentrations. The nursing and medical personnel looking after the patient in a hyperbaric chamber may suffer from decompression sickness due to tissue bubble formation. The risk is rather low because the chamber is kept warm; exposure is short and decompression rate slow. Risk of an accidental fire is greater in hyperbaric conditions. All inflammable material should therefore be kept away. Refractive changes and cataract in the lens of the eye may occur as a complication of prolonged HBO_2T. Claustrophobia may be a problem in up to 10% of patients, especially in the monoplace chamber.

HYPERBARIC CHAMBERS

The main facility required for hyperbaric medicine is of course the hyperbaric chamber itself. This is essentially a chamber constructed to withstand pressurization, so that oxygen can be administrated inside at a pressure greater than at sea level. The size, shape and pressure capabilities of the design chambers vary considerably. The technical details of each model, now available, are provided by the manufacturers and a classification of various types of chambers is shown here:

Types of Hyperbaric Chambers

a. Monoplace chamber (Fig. 153.1)
b. Multiplace or "Walk-in" chambers (Fig. 153.2)
c. Mobile or portable.
   Monoplace: Transportable by air, sea or land.
   Multiplace: A chamber can be driven from place-to-place.
d. Chambers for testing and training divers.
e. Small hyperbaric chambers.
f. For neonates.
g. For animal experiments.

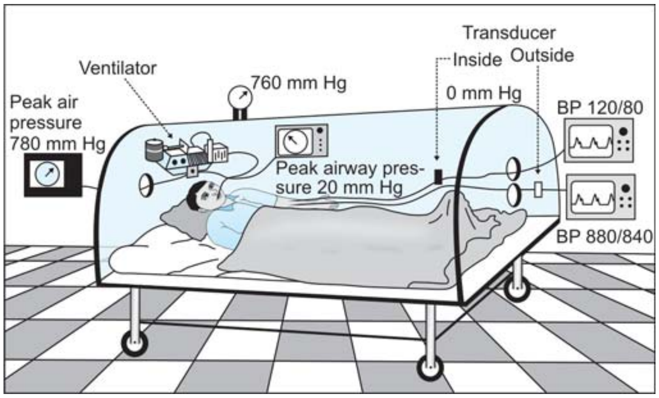

Fig. 153.1: A monoplace hyperbaric chamber

TECHNIQUES OF HYPERBARIC OXYGENATION

The hyperbaric technician follows the prescribed instructions for the hyperbaric physician about pressure, duration, and frequency of treatment. Most of the treatments are given at pressures between 1.5 and 2.5 ATA, and the usual duration of a hyperbaric session is 60 minutes. Of this, 10 minutes are required for compression, and 5 minutes for decompression if a pressure of 1.5 ATA is used. Thus, the maximal oxygen saturation is maintained for about 50 min. In the case of infections, the treatment duration is doubled. The treatment sessions for most chronic conditions are given daily, including on weekends.

World distribution of hyperbaric chambers: Some idea of the quantity of hyperbaric medical facilities in the world can be obtained by a review of the statistics regarding the distribution of hyperbaric chambers in various countries. Accurate information on this subject is difficult to obtain. The largest number of chambers is located in Russia (over 1200). South Korea has the largest number per million inhabitants (4.9 compared with 3.6 in Russia). Within Europe, excluding Russia, Italy has the largest number of installations (34.1% of the European total) and also the largest number per million inhabitants (1.75). The number of hyperbaric chambers per million inhabitants has risen progressively since 1968 in all countries except Germany, where the number has actually declined. The fastest rise has been in China and Japan. The number of chambers does not necessarily correlate with the number of treatments given. There is no separation of multiplace and monoplace chambers in the statistics.

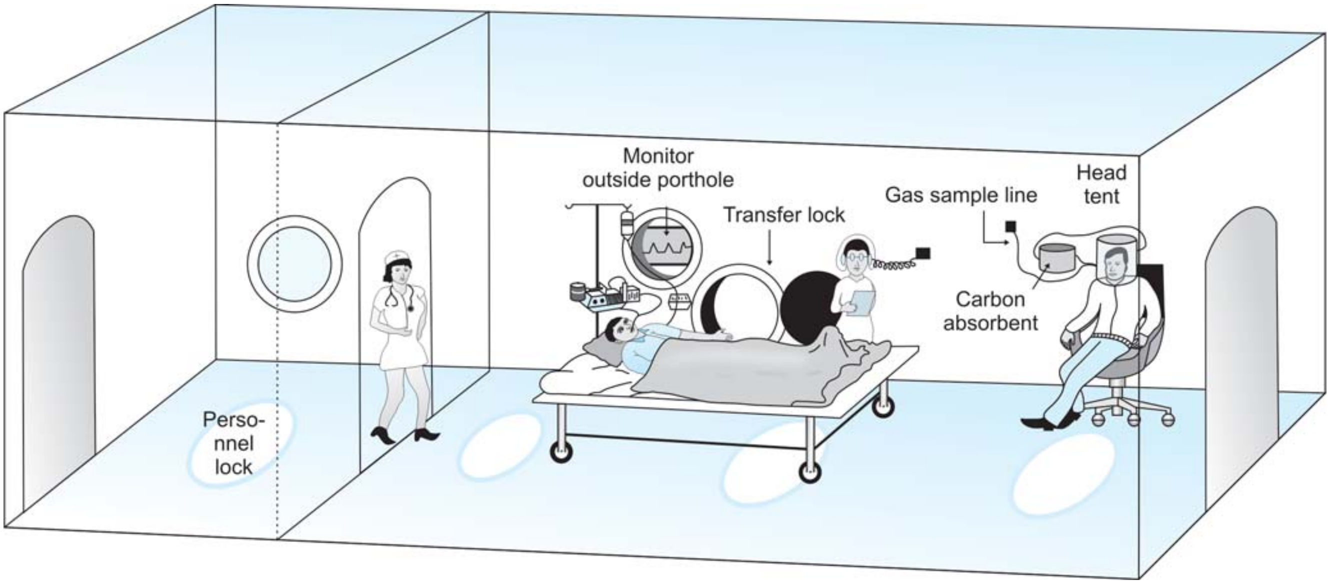

Fig. 153.2: A multiplace hyperbaric chamber

Hyperbaric Chambers in India: As the medical professionals in India are not all aware of the benefits of hyperbaric treatment, the availability of such facilities is also considerably less in number in India. Of 16 hyperbaric chambers in India, nine chambers are available with defence services, and seven chambers are with civil hospitals in metropolitan cities. Of course, the hyperbaric chambers available with the defence services are also being utilized by the civil population. But considering the magnitude of hyperbaric chamber requirements in India, for a billion population, the availability of chambers is grossly inadequate.

Pathophysiology of Pleural Effusion

Srinivas Rajagopala

INTRODUCTION: ANATOMY OF THE PLEURA

The thoracic cavity is constructed like a vertical bellow, with the diaphragm as its base. Within this limited protected cavity lie the two lungs, the heart, and the other mediastinal structures. To decrease the friction generated between the lung and the thoracic wall, during respiratory movements, the inner surface of the thoracic cage and the outer surface of the lungs and the mediastinum are covered by a serous, elastic membrane with a smooth and lubricating surface: the pleura. The pleural cavity is like a sealed, wet, and stretchable elastic bag inserted between the lung and the thoracic wall. The pleura is therefore, crucial for the efficient functioning of the lung.

The pleura is a serous membrane covering the lung, mediastinum, diaphragm, and rib cage. It can be divided into the visceral pleura and the parietal pleura; the former covers the lung parenchyma including the interlobar fissures and the latter lines the inside of the thoracic cavities. The parietal pleura is also arbitrarily classified into the costal, mediastinal, and diaphragmatic pleura according to the structure it invests. The visceral and the parietal pleura meet at the lung root. The surface area of the visceral pleura of one lung is similar to that of the parietal pleura of one hemithorax, approximately 1000 cm^2. The pleural pressure in humans is approximately –5 cm H_2O at mid-chest level at FRC and –30 cm H_2O at TLC. Pleural pressure varies by approximately 0.5 cm per cm height. The *Hydrostatic equilibrium model* and *Viscous flow model* have been proposed to explain why the vertical gradient is less than unity. A thin layer of fluid is normally present between the pleural surfaces to devoid of contact; the pleural space is thus, a "real" and not a potential space and this favors the viscous flow model.[1] This model states that the vertical pressure gradient is a consequence of the viscous flow generating a continuous column of fluid throughout the pleural space. This fluid acts as a lubricant, facilitates lung movement, and enables coupling of the lung with the chest wall.

Histology

The histology of the parietal pleura is fairly constant across species whereas, that of the visceral pleura varies significantly. The parietal pleura has five layers with a mean thickness of 20 to 25 µm, and is composed of loose, irregular connective tissue with blood vessels (capillaries and lymphatic lacunas), covered by a single layer of mesothelial cells.[2] Mesothelial cells may have a variety of functions important to pleural biology. Mesothelial cells can secrete and organize the extracellular matrix components. They also secrete neutrophil and monocyte chemotactic factors. Mesothelial cells also produce several cytokines like TGF-β, EGF and PDGF which are important in pleural inflammation and fibrosis. Microvilli are present on the surface of mesothelial cells and serve to increase the surface area for metabolic activity. Mesothelial cells produce hyaluronin but not mucin, express keratin microfilaments, stain negatively with epithelial-specific antibodies (Ber-EP4, B72.3, Leu.M1 and CEA) and stain positively for calretinin and mesothelin.[3]

Lymphatic lacunae are specialized lymphatics shaped like flat cisterns. Lymphoid cells form aggregates underneath mesothelial cells, forming raised structures called *Kampmeier's foci* which may have an immune function. Lymphatic plexus of the costal pleura drain along the intercostal nodes; those in the mediastinal pleura drain to the tracheo-bronchial and mediastinal nodes. The diaphragmatic pleura drains into the para-sternal, middle phrenic and posterior mediastinal nodes.

The visceral pleura may be thick (humans, sheep, cows, pigs and horses) or thin (dogs, cats and monkeys). This distinction is important physiologically because the blood supply is dependent on the thickness of the pleura. A thick visceral pleura is supplied by the bronchial (systemic) circulation, while a thin visceral pleura depends on the lung parenchyma for nutrition.[4] Only the parietal pleura contains sensory nerve fibers, supplied by the intercostal and phrenic nerves.

Pleural Fluid: Normal Volume and Cellular Contents

The small amount of pleural fluid that is physiologically present, is maintained by fluid exchange across the pleural membranes by the interplay of Starling's forces and lymphatic drainage:

$$\text{Fluid Movement} = L \times S\,[(P\text{cap}-P\text{pl})-\Sigma\,(\Pi\text{cap} - \Pi\text{pl})]$$

where P and C are the hydrostatic and osmotic pressures, respectively, within the capillaries (cap) and pleural space (pl), L is the hydraulic conductivity of the membrane, S is the surface area, and Ï is the osmotic coefficient for proteins.

Normal pleural fluid is a microvascular filtrate formed from the parietal pleural capillaries. It is drained predominantly via the parietal pleural lymphatic stoma.[5] The absorptive gradient in the visceral pleural capillaries and the active transport across mesothelial cells play only a small role.[4] Study of the normal volume and composition of pleural fluid in humans is limited by the difficulty of retrieval, without traumatically entering the pleural space. The disparity of data from animals reflects the difference in retrieval techniques (aspiration or lavage), fixation, staining, identification of cells and genuine interspecies differences. In summary, the amount of pleural fluid in animals varies from 0.04 to 0.60 ml/Kg, has the solute characteristics of interstitial fluid (protein 1 to 2 g/100 ml and total leukocyte cell counts of 1000 to 2500/µl). Most of the protein is composed of albumin (50%), globulins (35%) and fibrinogen.[6]

Limited human data is available on pleural fluid composition (Table 154.1).[7] This small amount of fluid is distributed uniformly along the pleural surface with an average thickness of 20 µm (thicker in dependant portions). The low pleural fluid protein (protein ratio 0.15 to 0.2) indicates a high degree of sieving of protein at the pleural microvasculature.[8]

TABLE 154.1: Composition of pleural fluid from human studies

Parameter	*Yamada et al*	*Noppen et al*
Technique	Puncture of pleural space in healthy soldiers	Thoracoscopic lavage of pleural space during sympthatectomy
Maneuver	Exercise to yield fluid (70%)	Urea used as endogenous marker for dilution
Amount retrieved	Few drops-20 ml	8.4±4.3 ml (0.26 ml/kg)
Total leukocyte count/µl	4500 (1700-6200)	1716
Monocyte %	53.7	75
Lymphocyte %	10.2	23
Mesothelial cells%	3	
Granulocytes %	3.6	
Not classified%	29.5	

Physiology and Pathophysiology of Pleural Fluid Turnover

Pleural fluid is formed by the parietal pleural capillaries. The constant pleural liquid production across species with differing visceral pleural thickness, the closer distance of parietal pleural microvessels (10 to 15 µm vs 20 to 25 µm in visceral pleura), and the higher venous pressure on the parietal pleural side all favor a systemic (parietal pleural) origin of the pleural fluid.[9] The pleural fluid protein decreases as the systemic blood pressure increases, also decreases with age (blood pressure increases and pulmonary resistance decreases with age). Fluid thus filtered, facilitated by the leaky nature of the mesothelial surface, and the strongly negative pleural pressures enter the pleural space. Minimally invasive studies in animals suggest that there is a gradual flow from top to bottom with a slow turnover (0.01 ml/kg × height with a half-time of 6 to 8 hours or about 15 ml in an adult male).

Pleural fluid is absorbed by bulk flow through the lymphatic stoma (2 to 6 µm) in the parietal pleura. Diffusion, active transport and transcytosis also contribute minimally to physiological turnover of pleural fluid.[10] Because of the "bulk flow" as the mode of absorption, the pleural fluid protein remains constant with absorption. This permits the use of concentration of protein in the pleural fluid to differentiate between exudates and transudates.[7] Transudative effusion results as a result of an imbalance between fluid formation at the parietal pleural capillaries, and via visceral pleura in conditions of interstitial fluid excess and removal via parietal lymphatics. Exudative effusion results from an abnormality in the pleural surfaces and an exudation of protein-rich fluid in the pleura. Most of the parietal pleural stoma are distributed dorso-caudally, the visceral pleura is devoid of stoma. Parietal pleural lymphatics have large reserve, can compensate for an increased production of pleural fluid by about 30 times, if absorption via the stoma is normal.

Physiological Changes with Pleural Effusion

When the pleural space is occupied by fluid, the pleural pressure becomes positive. The increase in volume must be compensated by an increase in the size of thoracic cavity [distending pressure = P(atm) – P(pleura)], or a decrease in size of the heart or lungs [distending pressure=P(alv) – P(pleura)].[11]

In experimental settings, the addition of saline in the pleural cavity causes 30% decrease in lung volume at functional residual capacity and 20% at total lung capacity. Therapeutic thoracocentesis has been shown to increase the FEV_1 and FVC by 200 ml for every 1000 ml removed fluid.[11] The increase in maximal inspiratory pressures post thoracocentesis, is greater than the improvement in lung volume; relief of the downward displacement of the diaphragm is probably responsible for this finding. Pleural effusion leads to an ipsilateral intra-pulmonary shunt, which does not significantly change after thoracocentesis. Consequently, PaO_2 does not increase after thoracocentesis, may actually decrease paradoxically. Exercise limitation in pleural effusions results from decline in lung volumes and cardiac function, as reflected by a reduced oxygen pulse. Therapeutic thoracocentesis, however, does not lead to any immediate improvement in exercise capacity as measured by VO_2 (max).[12]

Physiological Changes with Pneumothorax

When pneumothorax occurs, the pleural pressures become uniformly positive unlike in pleural effusion, in which a gradient exists from bottom to top. As a result, the upper lobe is affected more than the lower lobe in pneumothorax, whereas the lower lobes are more affected with pleural effusion. With pneumothorax, the increase in the volume of a hemithorax is four-fold less than the decrease in the volume of the lung. Hypoxemia occurs because of the presence of an intra-pulmonary shunt and due to reduced cardiac output in tension pneumothorax.[11]

Pleural Manometry

Direct measurement of pressures in the normal pleural space is technically challenging because of the close approximation of the two pleural surfaces. Accumulation of fluid leads to a wide range of pleural pressures depending on pleural, chest wall and lung compliances. An abnormally wide pleural space filled with fluid represents a hydrostatic gradient, when viscous flow resistance becomes negligible. Measurement of pleural pressures has several utilities in clinical practice. In general, pressures of less than –5 cm H_2O or pleural elastance (pressure change divided by the amount of fluid removed) of more than 25 cms H_2O/l suggest lung entrapment or atelectasis due to endobronchial occlusion. Pleural elastance can also guide therapeutic thoracocentesis since reperfusion pulmonary edema does not occur until pleural pressures are less than –20 cm H_2O.[13] Also, elastance can predict the success of pleurodesis since pleural opposition is unlikely, if lung entrapment exists.[14]

Pleural manometry can be performed with a vertical-column water manometer with an interposed resistive element or with a hemodynamic transducer connected to a standard physiologic system.[15] Pleural manometry can be easily performed in the absence of complex equipment using CVP manometers connected to a thoracocentesis catheter, inserted in the most dependent portion of the pleural effusion. The manometer is carefully zeroed and purged of air. Pleural pressure is reported as the mean pressure of the oscillating air column. Measurements are performed initially, and after each 250 ml of fluid that is withdrawn and elastance calculated. Coughing invalidates this measurement. The main advantage of water manometers is their conceptual simplicity. The disadvantages are primarily related to the difficulty in reading accurate values from the oscillating water column, and the unfavorable physical characteristics of water manometers. Electronic systems used in critical care units for hemodynamic measurements can also be used by zeroing at the level in which the thoracentesis catheter is introduced into the patient.

In summary, the pleura is a serosal membrane which functions to reduce the friction during lung movement. Normal pleural fluid is a microvascular filtrate formed from the parietal pleural capillaries, predominantly drained via the lymphatic stoma. Pleural manometry is increasingly used to diagnose trapped lung, predict success of pleurodesis and guide therapeutic thoracocentesis.

Approach to Pleural Effusion

George D'Souza

INTRODUCTION

Pleural effusion, the accumulation of fluid in the pleural cavity, is a common clinical problem encountered in general practice. Normally, the pleural space is a potential cavity encased between the visceral and the parietal pleura. The inner lining of the cavity is covered with a thin film of pleural fluid secreted by the microvilli of mesothelial cells.[1] This thin layer of fluid is essential for the smooth movement of lungs during respiration.[2] Based on chemical characteristics, normal pleural fluid is more representative of the interstitial fluid from the lungs than from the systemic circulation.[3] The fluid, protein and cells exit porous mesothelial cells of parietal and visceral pleurae flow, towards the dependent diaphragmatic pleura, where it passes through the stomata to exit the pleural cavity into the lacunae.[4, 5] Once in the lacuna, the fluid and the cells are drained into the lymphatic channels, which finally join the thoracic duct (Fig. 155.1).

MECHANISMS OF PLEURAL EFFUSION FORMATION

Based on the physiology of normal pleural fluid dynamics in animals, it has been postulated that excessive fluid accumulates in pleural space, due to excessive formation, inadequate drainage, or a combination of excessive formation and inadequate drainage.[6-8] Using a dual isotope method, it has been demonstrated that the mechanism for pleural fluid accumulation in metastatic lung cancer and pancreatitis is due to excessive formation of fluid from the leaky microvasculature, while there is decreased pleural drainage in mesothelioma. In heart failure, there is evidence for both excessive formation and decreased drainage, leading to fluid accumulation in the pleural space.[7] Different pathogenic mechanism have been proposed in the formation of pleural effusion in various clinical conditions (Table 155.1).

Clinical Approach

A good clinical history can facilitate the work-up of undiagnosed pleural effusion (Table 155.2). Although majority of patients report pleuritic chest pain, dyspnea or cough, a small proportion may have asymptomatic pleural effusion (Table 155.3). While persistent pleuritic chest pain may be a sign of mesothelioma or bone metastasis with pleural involvement, recurrent

- Yellow Nail syndrome

hemoptysis should alert the possibility of malignancy, tuberculosis or thoracic endometriosis in women. Also, clinical examination should be focused to elicit the following findings: Yellow nails in yellow-nail syndrome, clubbing in lung cancer, polyarthritis in rheumatoid arthritis and systemic lupus.

Physical examination findings vary with the amount of effusion and state of the underlying lung. The sensitivity and specificity of physical examination are comparable to those of chest radiography.[9] The usual clinical findings include: Diminished chest movement, stony dull percussion, with absent vocal fremitus and absent breath sounds. In the presence of hydro-pneumothorax, shifting dullness and succussion splash may be demonstrable. It is usual to hear egophony at the upper level of a large pleural effusion. Considerable amount of fluid can accumulate before a patient becomes symptomatic, especially if the contralateral lung is normal. Pleural fluid can accumulate following migration of fluid from the peritoneal cavity, as observed in hepatic hydrothorax, from pancreatic bed following pseudocyst formation and from extra-peritoneal extravasation around ureter, as in urinothorax.[10-12] Therefore, clinical examination of abdomen to look for ascites, pancreatic pseudo cyst and hydronephrosis are important in evaluating undiagnosed pleural effusion.

Imaging Studies for Pleural Effusion

Chest Radiography

A posterior–anterior (PA) view of the chest radiograph can show obliteration of costophrenic angle with more than 50 mL of fluid and a meniscus, when more than 200 mL of pleural fluid is present.[13] If pleural effusion is detected on PA view of a chest radiograph, the clinician should proceed with bilateral lateral decubitus views to demonstrate that the effusion is free flowing, as evidenced by layering of the effusion in lateral decubitus view.[14] If the height of the effusion on a lateral decubitus view is more than 1 cm, the effusion can be safely sampled. A large to massive pleural effusion usually causes a shift of the mediastinum to the opposite side. Absence of contra-lateral mediastinal shift with a large pleural effusion may indicate a fixed mediastinum due to an under lying malignancy.[2] The presence of pleural effusion with a shift of the mediastinum to the same side indicates concomitant atelectasis, due to lung fibrosis or the presence of intra-bronchial obstruction.

Presence of interstitial infiltrate and pleural effusion should alert the possibility of rheumatoid pleurisy, Systemic Lupus Erythematus (SLE), sarcoidosis, heart failure, lymphagioleiomyomatosis or lymphangitis carcinamatosis. Presence of hilar or mediastinal lymphadenopathy and effusion should raise the suspicion for tuberculosis, lung cancer, lymphoma and sarcoidosis, while bilateral effusion without mediastinal or hilar lymphadenopathy indicates a trasudative process, such as heart failure, nephrotic syndrome, hypoalbuminemia or constrictive pericarditis.

Ultrasound and Computed Tomography of Pleura

Ultrasound is a non-invasive tool commonly used to confirm the presence of pleural effusion and to aid thoracentesis, especially in the presence of loculated effusion.[15, 16] Computed Tomography (CT) of chest with contrast enhancement is essential for the evaluation of undiagnosed pleural effusion and for management of complicated parapneumonic effusion and empyema. A diagnosis of benign asbestos related pleural effusion can be made in a patient with appropriate history and demonstration of pleural plaques on CT chest.[17]

Thoracocentesis

Who needs a diagnostic thoracentesis? Any patient with undiagnosed pleural effusion should undergo a thoracentesis for laboratory investigations of the fluid (Table 155.4), provided the amount of pleural fluid is sufficient for drainage and there are no contraindications to thoracentesis. Nevertheless, if a patient has typical features of heart failure and pleural effusion, one may choose to observe effusion with follow-up chest X-ray to document resolution. Clinical features which should alert the clinician to proceed with thoracentesis in a patient with heart failure are: Presence of fever, pleuritic chest pain and X-ray evidence of large to massive effusion.[2] Physical appearance of the pleura can help in arriving at clinical diagnosis (Table 155.5). A putrid odor may indicate anaerobic empyema, while ammonia smell may point to urinothorax.

Diagnostic Classification of Pleural Fluid

Pleural fluid is classified as transudative or exudative, based on the biochemical and cellular features. In a trasudative effusion, the underlying pleural structure is normal and the fluid is formed because of an abnormal increase in pulmonary hydrostatic pressure, a decrease in plasma oncotic pressure or a combination of the two processes. However, in an exudative effusion, the integrity of pleura is abnormal due to an infection, infarction or infiltration, the principle process driving the effusion formation is not an elevated hydrostatic pressure, but an increase in vascular permeability. The diagnostic separation of pleural effusion into transudates and exudates was previously done using pleural fluid to serum total protein ratio, pleural fluid Lactate Dehydrogenase (LDH) to serum LDH ratio, and the absolute value of LDH.[18] These old criteria set in 1972, were critically assessed on the basis of results of a large cohort of patients with pleural effusion and were modified to the new criteria; pleural fluid absolute LDH value over 80% of the normal serum level or a Total Protein Ratio (TPR) over 0.5 for the diagnosis of an exudative pleural effusion.[19] Using pleural fluid to serum LDH ratio for the diagnostic separation can be confusing.[19-21] Finally, serum to fluid albumin gradient has no role in the routine diagnosis of transudates and exudates.[22]

The clinical utility of classifying pleural effusions into transudates and exudates relies on the convenience, that transudates are caused by a limited number of benign clinical conditions (Table 155.6), which require no further

invasive diagnostic procedures such as the pleural biopsy, or thoracoscopy.[2] Usually, transudates resolve with treatment of the underlying condition. An exudative pleural effusion (Table 155.7) requires further diagnostic testing if the physician cannot find a definite cause.

TABLE 155.8: Common causes of low pH pleural effusion

Tuberculous pleurisy	10

Additionally, an exudative pleural effusion secondary to primary lung cancer has grave prognostic significance, therefore the need to confirm the diagnosis before embarking on curative chemotherapy.

Pleural Fluid pH

Pleural fluid pH can be measured with a blood gas analyzer, normally it is alkaline at 7.64.[2] Pleural fluid pH should be routinely done on all thoracocentesis samples, as it helps to narrow down the differential diagnosis, to prognosticate the need for chest tube drainage in complicated parapneumonic effusion and to prognosticate the outcome of malignant pleural effusion. Urinothorax is the only transudative effusion with an acidic pH.[12] A low pleural fluid pH (Table 155.8) has been identified as the single most reliable predictor, necessitating chest tube drainage in a complicated parapneumonic effusion.[20,23-25] In a malignant pleural effusion, a lower pleural fluid pH is correlated with a higher tumor burden, and therefore with poor survival.[26] Finally, a lower pleural fluid pH has been associated with lower rates for successful pleurodesis in malignant pleural effusion.[27]

Pleural Fluid Glucose

Glucose is a small molecule that can easily diffuse across pleural membranes from plasma. Therefore, pleural fluid glucose mirrors the plasma glucose concentration. Interpretation of pleural fluid glucose should always be done with reference to plasma glucose. A low pleural fluid glucose is most often observed in empyema, complicated parapneumonic effusion, malignancy, rheumatoid pleurisy, systemic lupus and esophageal rupture.[2] A high glucose effusion designated as "Sweet hydrothorax" may indicate esophageal perforation in a patient receiving tube feeding, and in patients developing effusion, while on peritoneal dialysis.[28,29]

Total and Differential Cell Count

The total pleural fluid white cell count is seldom utilized in the evaluation, but a differential cell count is useful in narrowing the differential diagnosis of exudative effusion.[2] Neutrophil predominant pleural fluid observed in acute pleural inflammatory processes is mediated by interleukin-8 (IL-8), whereas monocyte chemotactic peptide 1 (MCP-1) mediates the monocyte predominance observed in malignant pleural effusion.[1] Following an acute pleural inflammation, polymorphonuclear cells tend to predominate within 24 hours to 48 hours of pleural fluid formation, thereafter the percentage of neutrophils begins to decline acutely, leading to the predominance of lymphocytes.[30] Therefore, the interpretation of pleural fluid differential cell count should be done with reference to the time of onset of pleural inflammatory processes leading to effusion formation.

Pleural effusions are classified arbitrarily as lymphocyte rich if the percentage of lymphocytes is more than 80%, neutrophil-predominant if the PMN's are more than 80% and eosinophilic if the percentage of eosinophils is more than 10%. The presence of even 1% of eosinophils in pleural effusion was diagnostic of coccidioidomycosis related pleural effusion.[31] One can clinically approach pleural effusion in a systematic fashion (Figs 155.2 to 155.4).

Hemorrhagic Pleural Effusion

In a case of hemorrhagic pleural effusion, the odds of malignancy are higher in the absence of trauma.[32] The diagnostic approach should include the exclusion of common benign causes, such as post coronary artery, bypass surgery, and pulmonary embolism (Fig. 155.5). Thoracic endometriosis should be considered in women during their reproductive period, especially if it occurs on the right side.[33]

TABLE 155.9: Causes of amylase rich pleural effusion

Pancreatic Type Amylase	*Salivary Type Amylase*
Acute pancreatitis	Adenocarcinoma of lung
	Squamous cell lung cancer
Chronic pancreatitis	Undifferentiated lung cancer
	Ovarian Cancer
Pancreatic pleural fistula	Multiple myeloma
	Lymphoma
	Lymphatic leukemia
	Pneumonia
	Tuberculosis

Pleural Fluid Amylase

An effusion is classified as "amylase rich", if the pleural fluid amylase value is more than the corresponding serum value or if the fluid to serum amylase ratio is over 1.[34,35] Occasionally, raised fluid amylase with normal serum amylase has been reported in pancreatitis related pleural effusion.[36] Amylase rich effusion has been observed in a variety of clinical conditions (Table 155.9) and therefore, determination of the pleural fluid amylase isoenzymes into pancreatic or salivary type will help to narrow the differential diagnosis.[34,37] The presence of

salivary amylase in pleural fluid suggests the diagnosis of malignancy in the absence of esophageal rupture,[34] the pancreatic type of amylase confirms a pancreatitis related pleural effusion.

Triglycerides and Cholesterol

Thoracentesis yielding milky fluid should alert the clinician concerning the possibility of chylothorax and pseudochylothorax (Table 155.10). Occasionally, chylothorax can be bloody, especially when it occurs following trauma; yellow to turbid appearing chylothorax has been also reported.[2,38,39] A diagnosis of chylothorax is highly likely, if the pleural fluid triglyceride concentration is more than 110 mg/dl.[40] A chylothorax can be ruled out if the pleural fluid triglyceride level is less than 50mg/dl. Pleural fluid electrophoresis is recommended for confirmation of chylothorax when the pleural fluid triglyceride level is between 50 mg and 100 mg/dL.[38,41] Presence of chronic inflammation as in rheumatoid pleurisy and tuberculosis can lead to accumulation of cholesterol crystals, causing a milky appearance of the pleural effusion called chyliform or pseudochylothorax.[2,42]

Pleural Fluid Immunology

Measurement of pleural fluid Anti Nuclear Antibodies (ANA) titer can be helpful in diagnosing systemic lupus related effusion. A pleural fluid ANA titer that exceeds 1:160 is diagnostic of lupus pleurisy.[43] However, a speckled pattern with low titers indicates an alternate diagnosis. Accordingly, it has been suggested that the pleural fluid ANA testing does not provide additional information in a patient with a clinical diagnosis of lupus.[44] Similarly, a pleural fluid rheumatoid titer exceeding 1:320 has been reported as diagnostic of rheumatoid pleurisy.[2] The role of newer tests such as measurement of anti-cyclic citrullinated peptide level in pleural fluid (anti CCP) has not been evaluated in the diagnostic work-up of rheumatoid pleurisy.

Measurement of pleural fluid Adenosine Deaminase (ADA) concentration is promising in the diagnosis of tuberculous pleurisy.[45-47] The increased pleural fluid ADA level results from an increased production of ADA by monocytes and macrophages sensitized to tuberculous antigens. Although the sensitivity of pleural fluid ADA has been shown to be over 90%, the specificity is low due to false positive results observed in effusions due to carcinoma, lymphoma, empyema, rheumatoid pleurisy, mesothelioma, and *Legionnella* pneumonia.[48] Measurement of pleural fluid ADA-2 isoenzyme concentration improves the diagnostic accuracy for tuberculous pleurisy.[49] Pleural fluid ADA measurement is recommended as a diagnostic test in countries with a high prevalence of tuberculosis.[50] However, its value in countries with low incidence of tuberculosis remains controversial.[51]

Pleural Fluid Cytology

Pleural fluid cytology is an integral part of work-up for exudative effusion. Cytology is helpful in arriving at a diagnosis of malignant effusion in over 60 to 80% of cases.[52,53] A cell block preparation fixed with formalin made from a centrifuged pleural fluid specimen increases the diagnostic yield for malignancy.[54] The use of multiple tumor markers in addition to cytology improves the yield.[55,56] Examination of pleural fluid for DNA methylation abnormalities has been shown to improve the sensitivity in diagnosing malignant effusions.[57] Cytological and immuno-histological examination of pleural fluid should be an essential tool in evaluating patients with Aqcuired Immunodeficiency Syndrome (AIDS), especially if fungal infection or primary pleural lymphoma is suspected.[58-60]

Pleural Fluid Culture

Pleural fluid cultures are positive for bacteria in 40 to 58% of patients with parapneumonic effusion (Table 155.11).[61,62] Part of the reason for poor yield is the prior antibiotic therapy. Interestingly, pleural fluid culture for

TABLE 155.11: Causes of bacterial parapneumonic effusion

anaerobic bacteria is positive in only about 20% of cases.[62] Pleural fluid nucleic acid amplification with bacterial probes improves the diagnostic yield of S. *Pneumoniae* related parapneumonic infection.[62] Pleural fluid pneumococcal antigen assay has been found to be useful in diagnosing *S. Pneumoniae* related parapneumonic effusion.[63]

Tuberculosis is the most common cause of exudative pleural effusion worldwide; one should process the fluid for smear and TB culture studies in all suspected cases of tuberculous pleurisy. Although the yield from the smear is low, the low cost and rapidity with which the diagnosis is made, makes this a useful test in the developing world. The reported yield from smear is about 5-20% in non-HIV patients and higher in HIV patients.[64] Positive pleural fluid culture is confirmatory for tuberculous pleurisy. Cultures for fungi should be processed in all suspected cases, especially in patients with AIDS, and parapneumonic effusion.[59]

Invasive Diagnostic Testing

Bronchoscopy

In the absence of hemoptysis, bronchoscopy has limited role in the investigation of pleural effusion.[65] Bronchoscopy is however required to investigate the airway and the lung parenchymal lesion suspected in the aetiology of effusion.

Pleural Biopsy

Closed pleural biopsy has been reported as a safe procedure in the diagnosis of exudative effusion.[66] The sensitivity can be improved to 80% by the modified Abram's technique, whereby suction is applied with the syringe during each biopsy and the needle is not removed from the thoracic cavity, until all biopsies are done.[67] The yield from biopsy with an Abram's biopsy needle was significantly better than biopsy with a true cut needle, when used with ultrasound guidance.[68] Based on a small series of patients with negative pleural fluid cytology, CT guided biopsy was reported to be better than the blind pleural biopsy.[69] Complications are rare, but serious intrathoracic hemorrhage can occasionally occur following closed pleural biopsy.[70]

Thoracoscopy

Thoracoscopy is now increasingly used for the evaluation of undiagnosed pleural effusion.[71] The advantages include the direct visualization of parietal and visceral pleurae, guided biopsies of lesions and for the lysis of adhesions. The mortality in experienced hands is about 0.24%.[72] The reported sensitivity for malignant and benign pleural disease was about 93% with 100% specificity.[72,73]

Pleural Manometry

Pleural manometry is useful in confirming trapped lung related pleural effusion. An increase in negative pressure of more than 15 cm per liter of removed fluid is diagnostic of trapped lung related pleural effusion.[74]

Approach to Pleural Disease in Acquired Immune Deficiency

Pleural effusions are common in acquired immunodeficiency syndrome (AIDS), the reported prevalence in hospitalized patients with AIDS varies from 7 to 27% .[75,76] Infections account for the majority of pleural effusions, about 30% of cases occur from non-infectious causes (Table 155.12).[59,75] The general approach is the same as described for non-AIDS patients. Nevertheless, the emphasis is laid on special staining techniques to identify fungal infections. In debilitated patients with hypoalbuminemia, it is prudent to use pleural fluid LDH rather than the total protein ratio for diagnostic separation of transudates and exudates.[77]

TABLE 155.12: Causes of pleural effusion in AIDS

Infectious Causes	*Non-Infectious Causes*
Parapneumonic effusion	Congestive heart failure
Septic embolism with empyema	Hypoalbuminemia
Bordetella bronchiseptica	Uremic pleurisy
Mycobacterium tuberculosis	Kaposis's sarcoma
Mycobacterium avium intracellulare	Lymphoma
Nocardiosis	Primary effusion lymphoma
Pneumocystis jirovecci pneumonia	ARDS
Cryptococcal infection	Atlectasis
Coccidioidomycosis	

Pneumocystis Jiroveci Pneumonia

Pneumocystis Jiroveci Pneumonia (PJP) related pleural effusion varies from 6 to 11% in hospitalized patients with HIV.[75,76] Pleural effusions are usually small to moderate in size, can occasionally be bloody. Pleural fluid LDH concentration is elevated and the differential cell count is predominantly mono-nuclear. A definite diagnosis of PJP effusion requires the demonstration of trophozoite or cyst forms of Pneumocystis in pleural fluid.[78] Grocott silver staining can improve the sensitivity by demonstrating the cyst forms of PJP.[78] The presence of trophozoite forms is best detected with an air-dried and Diff-Quik stained cytospin preparation.[79] The demonstration of granular eosinophilic aggregates, numerous vacuolated macrophages, and scattered benign mesothelial cell clusters in the pleural fluid are surrogate markers of PJP effusion. A clinical diagnosis of PJP effusion can be made, if the cyst form is identified in Bronchoalveolar Lavage (BAL) fluid and the effusion resolves with the specific treatment for PJP.

Tuberculosis

About 8-13% of pleural effusions in patients in India are caused by tuberculosis.[75,76,80,81] *Mycobacterium tuberculosis* is the most commonly identified agent, but Mycobacterium avium complex can occasionally cause pleural effusions.[75, 82] Acid-fast staining of pleural biopsy is likely to be positive in patients with AIDS.[83]

Cryptococcal Pleural Effusions

Pleural effusion usually occurs in association with radiographic parenchymal abnormalities in the non-AIDS population, isolated findings on chest radiograph can occur in AIDS.[75,84,85] *Cryptococcus laurentii*, a new strain, has been reported to cause pleural effusion in patients with AIDS.[86] The pleural fluid is a serous exudate with a low nucleated cell count, the culture is positive in 42% of cases. Identification of cryptococcal antigen in the fluid of non-AIDS patients has proved a rapid and specific test.[87] Pleural biopsy has been helpful in making a definite diagnosis.[88]

Histoplasma capsulatum

Histoplasma capsulatum can cause pleural effusion in the AIDS and the non-AIDS populations.[89,90] The effusion is serous or serosanguinous with a low number of nucleated cells. A cytocentrifuged pleural fluid specimen stained with Wright-Giemsa stain will demonstrate intracellular yeast typical of *Histoplasma capsulatum*.

Toxoplasma gondii

Toxoplasma gondii is a rare cause of pleural effusion, occurs in the late stages of AIDS.[91] A cytocentrifuged Giemsa-stained specimen of pleural fluid can demonstrate *T. gondii* tachyzoites within neutrophils.

Hypoalbuminemia

Hypoalbuminemia has been reported as a cause for pleural effusion in 7 to 15% of hospitalized patients with AIDS.[75] The effusion is a transudate, small to moderate in size, and bilateral. The nucleated cell count is low with mononuclear cell predominance.

Lymphoma

Lymphoma has been reported to cause pleural effusion in about 16% of patients with AIDS.[58, 82, 92] However, autopsy series have documented pleural effusion in over 65% patients. Isolated pleural effusion can occur as the sole manifestation of AIDS-related lymphoma without pulmonary parenchymal abnormality and lymphadenopathy.[93] The effusion tends to be large. Fluid chemistry is exudative with normal glucose and high LDH concentration.[94] Pleural fluid cytology clinches the diagnosis in about 60% of cases.[95] Flow cytometric examination of pleural fluid is useful in establishing the diagnosis in patients with a high index of suspicion for lymphoma.

Kaposi's Sarcoma

Pleural effusion occurs in 36 to 60% of patients with Kaposi's sarcoma.[96,97] Majority of patients will show pulmonary parenchymal infiltrates or lymphadenopathy. The pleural effusion is serosanguineous, free flowing and large. Chylous effusion has been reported in Kaposi's sarcoma secondary to lymphatic obstruction.[96,98] Pleural fluid cytology is seldom positive. Closed pleural biopsy is of no use, since the parietal pleural is not involved. The finding of characteristic cherry-red endobronchial lesions on bronchoscopy is helpful in making a clinical diagnosis.

Primary Effusion Lymphoma (PEL)

Primary effusion lymphoma has been reported as a unique entity in AIDS.[99] The majority of PEL exhibits indeterminate immuno-phenotypes, i.e. express CD45, CD138 and activation-associated antigens (CD30, CD38 and HLA-DR), lack surface expression of B cell markers (CD19, CD20, CD79a and immunoglobulin), but exhibit clonal rearrangements and somatic hypermutation of the immunoglobulin genes, suggesting that they take origin from post-germinal center B cells.[100] Although Kaposi's sarcoma-associated herpes virus has been suggested as the causative agent in PEL, concomitant presence of Epstein-Barr virus in most PEL suggests the role of Epstein-Barr virus as a co-factor in the development of PEL.[101]

PEL occurs predominantly in HIV-seropositive homosexual men between the age of 30 and 50 years.[102] Pre-existing Kaposi's sarcoma has been reported in about 33% of patients with PEL. Pleural effusion with parietal pleural thickening occurs in the absence of lung parenchymal lesions or mediastinal lymphadenopathy. Pericardial effusion and ascites are other common radiological findings. Peripheral lymphadenopathy and bone marrow involvement are unusual findings in PEL.[103] The most valuable marker for PEL is the demonstration of Kaposi's sarcoma-associated herpes virus-associated LANA-1 in the nuclei of most cells.[60]

Congestive Heart Failure

Transudative pleural effusion secondary to cardiac failure has been reported in hospitalized patients of AIDS.[59] Dilated cardiomyopathy, secondary to HIV, has been implicated as the cause of cardiac failure.[104]

In conclusion, pleural effusion is a common clinical problem of multiple etiologies that requires a systematic approach for a definitive diagnosis. Even after extensive investigations, about 10% cases remain undiagnosed. The first step is to classify the effusion into a transudate or an exudate, using the results of pleural fluid biochemistry. Total and differential cell count will help to narrow down the differential diagnosis. An elevated pleural fluid ADA is a useful test in the diagnosis of tuberculous pleurisy, in areas with high prevalence of tuberculosis. The diagnostic possibilities for pleural effusion in patients of AIDS are complex and require special staining techniques to rule out opportunistic infection and rare malignancies.

Tubercular Pleural Effusion

Pranab Baruwa, Kripesh Ranjan Sarmah

Pleural involvement in tuberculosis has been reported in approximately 5% of all Tuberculosis (TB) patients.[1] Apart from lymph node tuberculosis, pleural effusion is the second most common form of extra pulmonary tuberculosis.[2] Frequency of pleural involvement in TB is variably reported from 4% in US to 23% in Spain.[3,4] Incidence of TB pleural effusion in Acquired Immunodeficiency Syndrome/ Human Immunodeficiency Virus (AIDS/HIV) is also variably reported from 15 to 90%.[5, 6] Without treatment, TB pleuritis may resolve spontaneously but most of them develop active TB at a later date. Spontaneous resolution occurs in 4 to 16 weeks without treatment.[7,8] Of 141 cases of TB pleural effusion and positive tuberculin test followed from 1940 to 1944, 92 (i.e. 65%) developed some form of active tuberculosis.[8]

CD4$^+$ T cell
Interaction of MTB and CD4$^+$ T cell
Release of cytokines and delayed HSR
Inflammation within pleural space
Development of effusion

Fig. 156.1: Pathogenesis of tubercular pleural effusion

PATHOLOGY AND PATHOGENESIS

Pleural TB can be a manifestation of primary or post-primary disease.[1] In primary disease, rupture of sub-pleural foci occurs as the initial event.[9] Postprimary form is frequently associated with parenchymal disease like consolidation or cavity formation.[1] When TB pleural effusion occurs in the absence of radiologically apparent TB, it may be the sequel to a primary infection.[10,11] Delayed hypersensitivity plays a major role in the pathogenesis of TB pleural effusion. Hypersensitive reaction is initiated when tubercular protein gain access to pleural space in case of an infected individual. Tubercle bacilli in pleural space interact predominantly with CD4$^+$ T cells, resulting in delayed hypersensitive reaction (Fig. 156.1).[12] This leads to accumulation of fluid in the pleural space which is mostly exudative, but sometimes serosanguineous and contain few bacilli.[11,13] Fluid accumulates due to increased capillary permeability and impaired lymphatic clearance because of the occlusion of pleural stomata.[14] Pleural fluid predominantly contains neutrophils for the first 24 hours.[15] The neutrophils in the pleural space appear to secrete a monocyte chemotaxin that recruits monocytes to the pleural space, thereby contribute to the formation of granulomas.[15] In Bacillus Calmette-Guérin (BCG) model of experimental TB pleuritis, macrophages predominate in the pleural space from day 2 to day 5 after the initial neutrophil predominance.[15] After this period, lymphocytes are the predominant cells.[16] The late phase is denoted by marked CD4$^+$/CD8$^+$ cell response with release of interferon γ and granuloma formation.[17]

CLINICAL FEATURES

Unlike pulmonary TB, most pleural TB effusion manifest as acute illness. One-third of patients are symptomatic for less than 1 week and two-third for less than 1 month.[18] The average duration of symptoms before presentation is about 14 days for primary TB and 60 days in reactivation disease.[19] Asymptomatic effusion is a rare presentation.[20] Pleural TB has been considered a disease of young age, increased incidence is seen among middle aged people, 19% cases due to reactivation.[21] In general, patients with TB pleuritis are younger than patients with parenchymal disease. Patients with pleural effusion secondary to reactivation tend to be older than those with primary pleural effusion.[10]

The most common symptoms in pleural tuberculosis are cough (71 to 94%), fever (71 to 100%), chest pain (78 to 82%) and dyspnea.[22,23] The pleuritic pain usually precedes the cough. Usually, patients are febrile, but some may have normal temperature. TB pleural effusion is typically unilateral, small to moderate in size and usually occupy less than 2/3 of hemithorax.[24] Patients of tubercular pleural effusion with HIV positivity tend to be older, more likely to have fluid smear and culture positive for MTB[25] Moreover, HIV-positive patients tend to have positive pleural biopsy and show high incidence of disseminated disease than the non HIV cases.[25,26] Fever, dyspnea, night sweat, fatigue, diarrhea, marked tachypnea, hepatosplenomegaly, lymphadenopathy are other symptoms, more common in HIV-positive patients.

Physical examination of chest in a case of TB effusion is similar to that in any other types of pleural effusion. The percussion note over an effusion is usually dull. Auscultation characteristically reveals decreased or absent breath sounds. Near the superior border of the fluid, however, breath sounds may be accentuated and take a bronchial characteristic. This phenomenon has been attributed to the increased conductance of breath sounds through the partially atelectatic lung, compressed by the fluid. In case of a loculated effusion, the typical findings of pleural effusion may not be present.

Diagnosis

Pleural Fluid Analysis

TB pleural fluid is usually clear and straw colored, it can be turbid or serosanguinous, but rarely bloody. Effusion is usually exudative with pleural fluid protein of more than 3.5 gm/dl.[27] Pleural fluid LDH is usually high, in most cases more than 200 U/dl, the pH ranges from 7.3 to 7.4 (rarely over 7.4), although it can be less than 7.3 in approximately 20% cases.[28] The fluid glucose concentration is more than 60 mg/dl in 80 to 85% cases and less than 30 mg/dl in about 15% of cases.[21,24] The total cell counts are usually in the range of 100 to 5000 per dl with more than 90% lymphocyte in two-thirds of cases.[11] Although in the initial stages of illness (up to 1–2 weeks) there is neutrophil predominance, serial thoracentesis show shift to the lymphocyte predominance.[16,18,29] Presence of more than 5% mesothelial cell in the pleural fluid is rarely compatible with TB pleural effusion, most likely due to chronic pleural inflammation that prevents exfoliation of mesothelial cells into the pleural cavity.[30] HIV infected patients may have numerous mesothelial cells.[31] Similar reports are also seen in immune-competent patients.[32] Pleural fluid eosinophilia (more than 10%) reduces the possibility of TB, provided the patient does not have a concomitant pneumothorax or had a previous traumatic thoracentesis that had resulted in hemorrhage within pleural space.

Adenosine Deaminase Enzyme Activity

Adenosine Deaminase (ADA) is an enzyme in purine salvage pathway that catalyzes the conversion of adenosine and deoxyadenosine to inosine and deoxyinosine with release of ammonia. Although wide in distribution, it plays an important role in the differentiation of lymphoid cells and is more abundant in activated T lymphocytes.[33] High levels of ADA are reported in patients with TB pleural effusion.[34] ADA level of more than 70 IU/L is highly suggestive of TB while a level of less than 40 IU/L virtually excludes the diagnosis.[35] A meta-analysis of 40 studies from 1966 to 1999 showed ADA sensitivity of 47.1 to 100% and specificity of 0 to 100%.[36] Several Indian studies have also reported similarly variable results.[37-39] These discrepancies in results from different studies are attributable to different methods of ADA analysis. Specificity increases when the lymphocyte to neutrophil ratio in the pleural fluid (more than 0.75) is considered in conjunction with an ADA concentration of more than 50 IU/L.[40] When prevalence of disease is low (i.e. less than 1%), the positive predictive value may also be as low as 15%, however negative predictive value increases.[41]

In areas with high prevalence of tuberculosis, ADA measurement is inexpensive, minimally invasive, rapid and readily accessible test that has sensitivity and specificity of 95% and 90%, respectively.[11,42] Elevated ADA in lymphocyte rich pleural fluid has been reported in other diseases, such as rheumatoid arthritis, bronchoalveolar carcinoma, mesothelioma, *Mycoplasma* and *Chlamydia pneumonia,* psittacosis, paragonimiasis, infectious mononucleosis, brucellosis, Mediterranian fever, histoplasmosis, coccoidiodomycosis and in most patient with empyema.[33,41,42] Of the two isoenzymes, ADA1 is found in all cells with highest activity observed in lymphocytes and monocytes. On other hand, ADA2 isoenzyme is predominantly found in monocytes/macrophages. ADA2 isoenzyme is primarily responsible for increased ADA activity in TB pleural effusion with median contribution of 88%.[43] Therefore, pleural effusion with high ADA level and ADA1/total ADA ratio less than 0.45, makes the diagnosis of TB highly likely.[44] The levels of ADA in patients of TB effusion with or without AIDS are comparable.[45]

Radiological Investigations

Radiological evaluation for pleural effusion is done with the help of chest X-rays, Computed Tomography (CT) scans and ultrasonography. Radiological findings are usually similar in pleural effusion of different etiologies. They can be suggestive but not specific to tuberculosis. Chest X-rays reveal usually unilateral small to moderate effusion (Figs 156.2 and 156.3). The classical X-ray picture in posteroanterior projection is the obliteration of the lateral Costophrenic (CP) angle with high density laterally with a gentle, medial, downward curve and a smooth, meniscus shaped upper border which terminates at the mediastinum (Fig. 156.4). In supine posture, there are signs of increased homogeneous density superimposed over the lung, loss of hemidiaphragm silhouette, apical capping, elevation of hemidiaphragm, blunting of CP angle, decreased visibility of lower lobe vasculature and accentuation of minor fissure.[46,47] An amount of 175–525 ml of fluid produces noticeable increase in density over lower lung zone on supine radiograph.[47] The lateral decubitus view shows homogeneous density with a straight horizontal superior border between the dependent chest wall and the lower border of the lung, provided the accumulated fluid is not loculated (Fig. 156.5). Minimum of 75 ml fluid is required to obliterate the posterior CP angle (Fig. 156.3). Sometime, pleural effusion may present as subpulmonic or loculated effusion. Rarely, pleural TB may present as pleural nodules and thickening.[48]

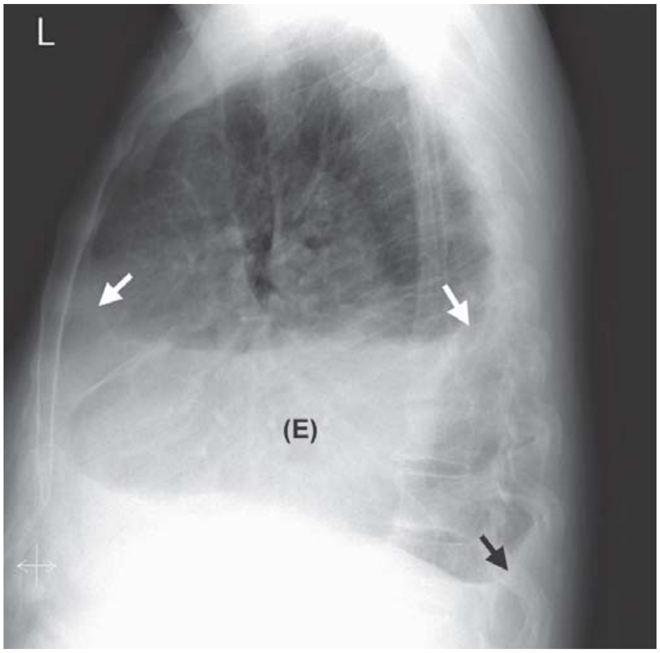

Fig. 156.2: Lateral view showing effusion in posterior CP angle

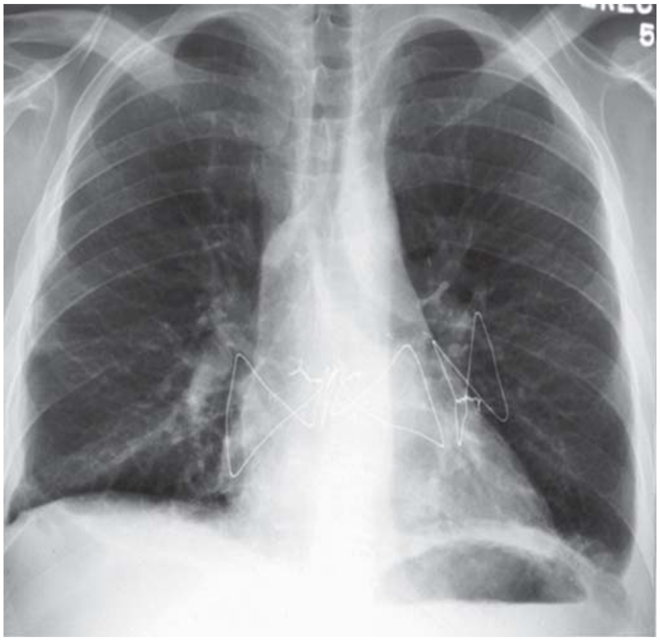

Fig. 156.3: PA view showing minimal left sided pleural effusion

On CT scan, the typical finding of free flowing pleural fluid is seen as a sickle shaped opacity in the most dependent part of the thorax, posteriorly (Fig. 156.6).[49] CT scan is also helpful to demonstrate pleural loculation

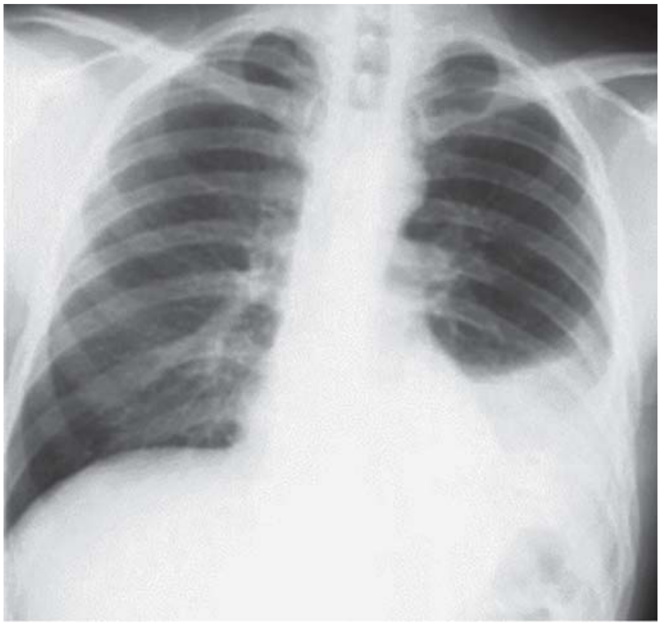

Fig. 156.4: PA view showing left sided moderate pleural effusion

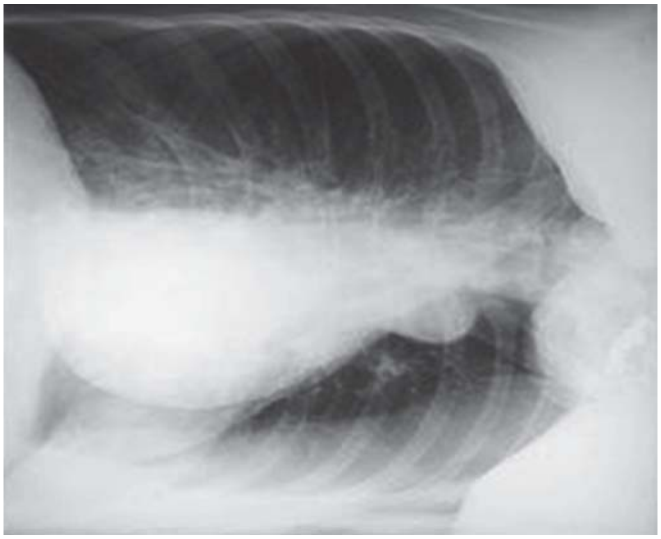

Fig. 156.5: Lateral decubitus view showing horizontal fluid level

(Fig. 156.7), as well as to see the associated parenchymal and pleural pathology (Fig. 156.8). Associated parenchymal lesions are seen in 20–50%, or even to 67% patients.[50-52] Lung parenchymal lesions have been observed in 86% of patient with TB pleural effusion using CT scans, 37% show features of radiologically active pulmonary TB.[52] Computed tomography can also help to detect other complications associated with TB pleural effusion, such as the pleural thickening, calcification,

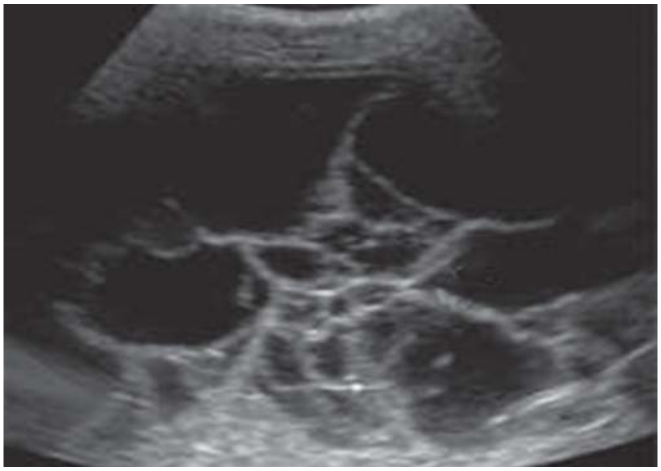

Fig. 156.9: USG showing multiple loculated pleural effusion

loculated effusion, empyema, empyema necessitans and bronchopleural fistula.[53]

Ultrasonography (USG) is a useful modality in the evaluation of pleural diseases.[54-56] It helps to differentiate pleural fluid from pleural thickening, helps in guided thoracentesis, identification of loculations (Fig. 156.9) and for differentiation of pyopneumothorax from lung abscess. USG is also useful to demonstrate fibrin bands of varying length, mobile delicate septation, encysted pleural effusion, pleural thickening and pleural nodules.[57]

Sputum Examination

Sputum examination, both smears and culture are generally not rewarding. Smears of sputum are rarely positive in primary cases, cultures are positive in only 25 to 33% of patients, especially if there is an associated underlying lung disease. In its absence, sputum examination may be positive in only 4 to 10% cases.[50,58,59] Induced sputum culture is positive in 52% and smear in 12% of cases.[60] Even in patients with normal lung parenchyma on chest X-ray, the yield of induced sputum examination in tubercular pleural effusion approaches 55%.[60]

Tuberculin Test

Positive tuberculin test constitutes a supportive evidence for tuberculosis. Negative tuberculin test in tubercular pleural effusion is attributed to anergy secondary to immunosuppression or malnourishment, recent infection, circulating mononuclear cells suppressing the specifically sensitized circulating T-cells in the peripheral blood or sequestration of tuberculin reactive T lymphocytes in the pleural space.[61,62]

Pleural Fluid Culture and Smear

Pleural fluid of tubercular origin contains fewer bacilli, detects AFB in less than 10% of cases.[21,22,24,35] In patient with HIV co-infection, the yield is over 20%.[25] Culture which requires a minimum of 10 live bacilli to 100 live bacilli, is positive in 12–70%.[22] Culture sensitivity can be increased by bed side inoculation of fluid, by using liquid media.[63]

Pleural Biopsy

Pleural biopsy reveals granulomas in 50–97% of patients with TB pleural effusion. When both biopsy and culture methods are used together, the diagnostic yield is high, from 60 to 95%.[20, 21, 24, 35, 50] Other causes of granulomatous pleuritis, such as the fungal disease, sarcoidosis, rheumatoid arthritis, and nocardial infection need to be excluded.

Thoracoscopy

Thoracoscopy is useful for direct pleural visualization. TB pleuritis may be seen as yellow white tubercles on the parietal pleura, reddening and adhesions. Thoracoscopy has been reported to be the most accurate, yet an invasive and expensive tool for establishing the diagnosis with a diagnostic accuracy of 100% on histology and 76% positive on culture.[64]

Miscellaneous Indirect Investigations

Interferon Gamma Assay: Interferon Gamma (IFN-γ) is produced by CD4 lymphocytes in patients with TB pleuritis. A cut off level of 3.7 IU/ml has shown both sensitivity and specificity of 98%.[65-71] Other diseases that can cause elevated levels of IFN- γ in pleural fluid include hematogenous malignancy and empyema.[66-68] Immunosuppressed patients have similar level of IFN-γ as the immune-competent.[66] Both ADA and IFN-γ has shown accuracy in detecting TB pleural effusion, the joint sensitivity and specificity of 93% for ADA and 96% for IFN-γ.[72] Although, a few studies have shown IFN-γ level to be more sensitive and specific than ADA, it is more expensive and less readily available than ADA estimation.[72-74] Pleural fluid IFN-γ estimation does not seem a cost-effective investigation for differentiating TB from non-TB effusion, compared to ADA in resource limited countries.[75]

Other cytokines: The serum to pleural fluid IL-6 level is significantly higher in TB effusion rendering it a novel marker in the differential diagnosis of exudative pleural effusion.[76] IL-1α and TNFα produced predominantly by mononuclear phagocytes have been shown to be present in tubercular, malignant and parapneumonic effusions with considerable cut-off levels for these diseases.[76,77] Levels of soluble IL-2 receptors, IL-18, immunosuppressive acidic protein and IL-12p40 are all significantly elevated in TB pleural effusion in a decreasing order of sensitivity, with soluble IL-2 receptor being a more sensitive marker than ADA.[78] These markers need further evaluation for routine clinical use.

Polymerase Chain Reaction (PCR)

PCR can detect as few as 10 bacilli.[79] For diagnosis of pleural TB, the test shows a sensitivity ranging from 20 to 90% and specificity 78 to 100%.[80-89] PCR finding are positive in 100% culture positive pleural TB and in only 30 to 60% of culture negative fluid.[35,83] False positive results are seen due to DNA contamination or presence of non-viable organisms. PCR of pleural biopsy tissue has 90% sensitivity and 100% specificity, the overall accuracy is similar to that of biopsy.[84]

Immunodiagnosis

Several immunological markers of tuberculosis such as IgA against MPT 64 and MT-10.3, anti IgM and IgG antibodies against anti-A60 and others have been evaluated for diagnosis.[85-87] Serum antibody levels against TB antigens have poor sensitivity and specificity, the performance of serological tests for diagnosis of TB pleuritis has been disappointing, regardless of HIV co-infection.[88]

Neopterin

Neopterin is a marker of Th1 immune-activation, it is secreted by activated macrophages.[89] Neopterin level in pleural fluid have been found to be higher in patients with TB than in patients with malignancy or other conditions.[90-92] Very high levels have been observed in uremic pleural effusions, raising doubts about its specificity for TB.[93] When histological evidence of caseating granulomas was used as the reference standard for TB, sensitivity and specificity of neopterin were found to be 44% and 85%, respectively.[91]

Leptin

Leptin is a 16kDa product of obese (ob) gene and may be involved in cross regulation between nutritional status and the immune response in TB.[89] Serum leptin level has been shown to be reduced in patients with active pulmonary TB and cancer.[94,95]

Lysozyme

Lysozyme is present in the epithelial cells of granulomas, macrophages and activated granulocytes. A value of 1.2:1 for ratio of pleural fluid to serum lysozyme has been proposed as a good test for diagnosing TB pleural effusion.[96]

Complement Activation

Complement plays an important role in the pathogenesis of tubercular pleural effusion. Complement activation in the pleural fluid of 83 patients measured by using commercial ELISA tests had a sensitivity of over 80%.[97]

Cell Subsets

TB pleural effusions are usually rich in mononuclear cells.[98] Although the pleural ADA activity correlated with the number of $CD4^+$ T cells in the pleural space, the number of pleural $CD4^+$ T cell was not an accurate diagnostic test for TB.[99]

Scoring Systems

There are limitations of individual tests used for the diagnosis of TB pleural effusion. Therefore, several scoring systems have been developed based on multiple tests.[100] In one of the model, the parameters of ADA, age, temperature and pleural fluid RBCs were used to predict tubercular etiology.[100] In the second model, all of the parameters of first model except ADA were used with addition of "no history of malignancy", pleural protein and pleural to serum LDH ratio.[100] Summated score of at least 5 in model one and at least 6 in model two had sensitivity of 95% and 97% and specificity of 94% and 91%, respectively. In another study, sensitivities for ADA activity, IFN-c levels and PCR of 88%, 91% and 74%, respectively and the specificities of 86%, 97% and 90%, respectively were used; when all the three variables were combined, the sensitivity and specificity increased.[101] There are several other models employing combination of ADA and neutrophil to lymphocyte ratio; duration of symptoms, pleural protein level, leukocyte count, percentage of lymphocytes and ADA, which have shown promising results in the preliminary studies.[102,103]

Future Diagnostic Modalities

Several new TB diagnostic modalities have been developed in the recent time - the loop-mediated isothermal amplification, detection of LAM (a TB antigen) using ELISA, phage-based assays and rapid culture systems.[104,105] However, these tests are not evaluated adequately for TB pleuritis.

HIV Infection and Pleural TB

Pleural tuberculosis in HIV positive patients occurs in the younger age group.[106] Patients with HIV/AIDS tend to have a longer duration of illness and lower incidence of chest pain.[107] Systemic signs and symptoms, such as night sweats, fatigue, diarrhea, hepatomegaly, splenomegaly and lymphadenopathy are significantly more common in HIV infected patients.[108] They are also more likely to have concomitant parenchymal lesion.[109] Their pleural fluid is more likely to be smear and culture positive for AFB.[107,110] If CD4 count is less than 100, approximately 50% will have positive smear for AFB in their pleural fluid and these patients have significantly lower lymphocyte count.[110]

Patients with HIV/AIDS and TB pleural effusions are treated with the same drugs for the same duration, as those with HIV negative status.[111] HIV positive persons with tuberculosis and all TB patients living in the HIV-prevalent settings should receive daily TB treatment, at least during the intensive phase as per the WHO guidelines, 2009.[111] One should be aware of drug interactions between the antiretroviral therapy (ART) and the anti tubercular drugs, adverse drugs reactions and the immune reconstitution syndrome. The later is manifested by the worsening of symptoms, an increase in the volume of existing pleural fluid or development of pleural effusion during treatment. Co-trimoxazole preventive therapy should be initiated in all HIV-positive TB patients, as soon as possible and given throughout the period of anti-TB treatment.[111] Continuation after completion of TB treatment can be considered in accordance with national guidelines. Antiretroviral therapy improves survival in patients with TB and HIV coinfection.

MDR-TB and Pleural Effusion

Drug resistance in pleural tuberculosis follows similar pattern to that of parenchymal TB.[112] Therefore, drug susceptibility testing is sought in areas where there is high incidence of resistance. Multidrug-resistance occurs in only 1% of patients with pleural TB, any 1st line drug resistance occurs in less than 10%.[112] The drug resistant patients are treated according to the culture and sensitivity pattern of the bacilli.

MANAGEMENT

The major objectives of treatment lie in the resolution of effusion, healing of active lesion and prevention of subsequent reactivation of tuberculosis. The other objectives of management are to prevent development of pleural fibrosis and to treat complications that may develop due to pleural effusion. The treatment can be broadly divided into medical and surgical management. A large majority of patients require only the medical treatment.

Medical Management

Tubercular pleural effusion is a type of extrapulmonary paucibacillary, disease. With adequate antitubercular treatment, most cases resolve completely with fewer chances of recurrence. According to the Revised National Tuberculosis Control Program (RNTCP) guidelines in India, the severely ill patients with extensive or bilateral pleural effusion are given treatment under category I which includes a thrice weekly regimen containing isoniazid, rifampicin, pyrazinamide and ethambutol, for initial two months followed by isoniazid and rifampicin for four month $[2(HRZE)_3/4(HR)_3]$ under direct supervision.[113] Unilateral or minimal TB effusions are given treatment under category III with thrice weekly isoniazid, rifampicin and pyrazinamide for the initial two months, followed by isoniazid and rifampicin for four months $[2(HRZ)_3/4(HR)_3]$ under direct supervision. Other guidelines have also recommended similar regimen, daily or thrice weekly.[114-116]

The WHO tuberculosis treatment guidelines 2009 recommend that both pulmonary and extrapulmonary tuberculosis need to be treated alike.[111] Patients should be categorized as new and previously treated. Thus, all new patients, irrespective of pulmonary or extrapulmonary TB, should receive a regimen containing 6 months of rifampicin and isoniazid. New patients may receive a daily intensive phase followed by three times weekly continuation phase $[2HRZE/4(HR)_3]$, if each dose is directly observed. Three times weekly dosing directly observed throughout therapy $[2(HRZE)_3/4(HR)_3]$ is another alternative, provided the patient is not living with HIV or in an HIV-prevalent setting. If there is high degree of isoniazid resistance, new TB patients should receive HRE in the continuation phase as an acceptable alternative to HR.[111]

The penetration of isoniazid in the pleural fluid is excellent, as of pyrazinamide is very poor, whereas the penetration of rifampicin is intermittent.[117] An average patient with TB pleural effusion becomes afebrile within 2 weeks of starting chemotherapy, but temperature elevations may persist for as long as 2 months.[118] Patients do not require any bed rest and need isolation only when there is associated parenchyma disease with positive sputum.[119] The incidence of pleural thickening at 6–12 months after beginning of therapy is approximately 50%. Residual pleural thickening is not related to the initial pleural fluid findings, patients with low glucose, high LDH and high cytokine level are only slightly more likely to have residual thickening.[120,121] However, in patients with loculated pleural effusion, there can be delayed resorption, even after completion of 6 month of treatment.[122]

Role of Corticosteroid

Prednisolone in a dose of 0.5 to 1 mg/kg per day has been used for a period ranging from 4 to 12 weeks, for an early resolution of clinical symptoms and signs (fever, chest pain and dyspnea).[123] Use of steroid has demonstrated a trend towards less residual pleural fluid at the end of treatment but there has been no difference in the development of residual pleural thickening or adhesion. There is insufficient data to determine whether steroids are effective in the treatment of TB pleural effusion.[124] The use of steroids in HIV/AIDS associated TB pleural effusion is not currently recommended because of the lack of survival benefit and an increased risk of Kaposi sarcoma.[125]

Role of Surgery

The emergence of drug resistance has redefined the role of surgery. Surgical intervention is required in a few cases of failure of medical therapy, complication of scarring and to establish a proper diagnosis.[126] Pleural effusion remain undiagnosed in 25% cases after routine investigations, this can be reduced to 4% by thoracoscopic biopsies.[126] Diagnostic, as well as therapeutic thoracentesis is the most common surgical procedure. Decortication is required when pleural thickening persists and causes significant clinical symptoms. Surgical interventions are also required for complications of empyema, bronchopleural fistula and others.

COMPLICATION OF TB PLEURAL EFFUSION

Pleural Thickening and Fibrothorax

Tubercular pleural effusion can lead to residual changes ranging from minimal pleural thickening to fibrothorax.[127] Fibrothorax may be associated with extensive volume loss of the underlying lung and ventilatory impairment.[128] Dull ache, heaviness and chest pain are other common complaints.

Empyema (Chronic Persistent Pleural Effusion)

Chronic TB empyema represents chronic, active infection of pleural space. Such complication can occur due to progress of primary TB effusion that is usually moderate to large in size. Empyema can also form due to direct extension of infection from thoracic lymph nodes or subdiaphragmatic foci, through hematogenous spread and following pneumonectomy. Chronic TB empyema may present as an abnormality on routine chest X-ray with bronchopleural fistula or as empyema necessitans.[129] Besides antituberculosis chemotherapy, intercostal tube drainage is necessary. Decortication, extrapleural pneumonectomy or thoracoplasty may also be required.

Empyema Necessitans

Empyema necessitans is formed by the break of empyema through the parietal pleura for spontaneous discharge of its content. It is usually formed in the subcutaneous tissues of the chest wall, but may sometimes occur at other sites, such as the esophagus, breast, retroperitonium, flanks, groins, pericardium and vertebra.[130] Surgical drainage is required, along with routine antitubercular treatment. Certain rare complications of tuberculosis include pseudochylothorax and chylothorax formation.[131-133]

Bronchopleural Fistula (BPF)

It is the direct communication between the pleural cavity and the bronchial tree or the lung parenchyma. Due to the effective modern antitubercular chemotherapy, BPF is an uncommon complication in current era. Fistulas are seen with old healed TB and after therapeutic pneumothorax, not followed by proper treatment.[134-136] Patients present with variable amounts of sputum production and fluctuating air fluid levels on serial X-rays. Confirmation of diagnosis can be made by injecting the methylene blue dye in the pleural space and demonstrating its presence in sputum or in the trachea-bronchial tree. Treatment requires adequate ATT, followed by surgical management.

In conclusion, TB pleural effusion is the second most common extrapulmonary form of tuberculosis. Patients usually present with acute illness, in most cases it is self-limiting. With adequate treatment, the outcome is usually good and the complications are few.

Parapneumonic Effusion and Empyema

Devasahayam J Christopher

INTRODUCTION

Pleural effusion frequently accompanies bacterial pneumonia occurring in up to 40% of hospitalized patients.[1] Bacterial pneumonias continue to be a cause of morbidity and mortality despite the availability of effective antibiotics and their widespread use. In the US, the annual incidence of bacterial pneumonia is around 4 million and a quarter of them require hospitalization.[2] Thus, the annual incidence of Parapneumonic Effusion (PPE) would amount to be substantial. Hospitalized patients with pleural effusion, accompanying bacterial pneumonias are 2.7 times more likely to have treatment failures than those without accompanying effusion.[3] Although PPE normally responds to antibiotic therapy, non-responsive effusions may progress to become purulent. Some of the increased morbidity and mortality in PPE occurs due to the mismanagement of pleural effusion.[4]

Historically, the first description of pleural infection has been ascribed to the Egyptian physician Imhotep around 3000 BC. It was Hippocrates in 500 BC, who recommended open drainage for the management of empyema.[5] This practice was replaced by the present day treatment of closed tube drainage only in the latter part of the 19th century.[6] Hippocrates also appeared to have understood that open drainage would be dangerous if the fluid had not become purulent. Enzymatic adhesiolysis for the management of loculated PPE was first described in 1950.[7] In the past two decades, people have used Video Assisted Thoracic Surgery (VATS) for the management of loculated PPE.[8]

DEFINITIONS

Empyema

Empyema is defined as pus within the pleural space. In its development, pleural fluid passes through stages of increasing host-defense activity and bacterial invasion. Not all infected pleural effusions progress to empyema.

Parapneumonic Effusion

Any pleural effusion associated with bacterial pneumonia, lung abscess or bronchiectasis is a PPE.

Complicated Parapneumonic Effusion

Complicated PPEs are conditions that do not resolve without therapeutic thoracentesis or tube throracostomy. Some of these are purulent (empyemas), while others have non-purulent pleural fluid.

PATHOGENESIS

The formation of an infected pleural space is a complicated interaction of the host defense mechanisms and the organisms. There are three distinct pathophysiological stages in PPE, reflecting the changing physiology within the pleural space. The distinctions between the stages are not sharply demarcated. There are different characteristics of pleural fluid seen during the different stages of PPE (Table 157.1).

TABLE 157.1: Characteristics of parapneumonic pleural effusions

Stages	*Macroscopic appearance*	*Pleural fluid characteristics*
• Simple parapneumonic	Clear fluid	pH >7.2 LDH <1000 IU/l Glucose >2.2 mmol/l No organisms on culture or Gram stain
• Complicated parapneumonic	Clear fluid or cloudy/turbid	pH <7.2 LDH >1000 IU/l Glucose >2.2 mmol/l May be positive Gram stain/culture
• Empyema	Frank pus	May be positive Gram stain/culture

LDH = lactate dehydrogenase

Adapted with permission from CWH Davies, FV Gleeson, RJO Davies, BTS guidelines for the management of pleural infection. Thorax 2003;58 (Suppl II):ii18–28[35]

Exudative Stage

This stage is characterized by accumulation of sterile fluid within the pleural space. This is in response to inflammation induced by bacterial infection within the lung parenchyma and the pleural membranes. Proinflammatory cytokines, such as interleukin-8 (IL-8) and Tumor Necrosis Factor-alpha (TNF-α), are released locally.[9] These probably act on the mesothelial cells and the capillaries within the visceral and the parietal pleura, leading to increased tissue and capillary permeability. The pleural fluid at this stage is a combination of interstitial tissue fluid and the microvascular exudate, characterized by low Lactate Dehydrogenase (LDH), normal glucose levels, and is not infected. If appropriate antibiotic therapy is instituted, the effusion is likely to resolve and intercostal drainage is not required.

Fibrinopurulent Stage

The fibrinopurulent stage occurs in response to bacterial invasion, usually as a consequence of inadequate or inappropriate therapy. Early on, there is increase in pleural fluid which contains polymorphs, bacteria and cellular debris. Later, there is formation of fibrin clots and fibrinous septae due to clotting factors from the serum entering the pleural space. This results in a heavily loculated pleural space that may be resistant to drainage with a single intercostal tube. As infection progresses, the pleural fluid pH and glucose levels reduce and LDH level goes up. Pus is formed by the lysis of bacteria and inflammatory cells.

Organizational Stage

The last stage is characterized by fibroblast proliferation and deposition of fibrous tissue on both the visceral and the parietal pleural membranes—the inelastic "pleural peel". This results in restriction of lung expansion and impairment of gas exchange. If untreated, there is potential for chronic infection resulting in penetration of fluid into the chest wall (empyema necessitans) or into the lung, resulting in a bronchopleural fistula.[10] The further course after organization is variable, some individuals undergo spontaneous healing with resolution of pleural thickening, others are left with "pleural peel".[11]

EPIDEMIOLOGY

Pleural infection is usually a complication of bacterial pneumonia. Independent risk factors for empyema include diabetes mellitus, alcohol abuse, gastroesophageal reflux disease, and intravenous drug abuse.[12] Empyema occurs more commonly during childhood, and in the elderly.[13, 14] Poor dental hygiene and aspiration may predispose to infection with anaerobic organisms.[15] It should also be appreciated that empyema can occur without an underlying bacterial pneumonia.[16-18] These may occur as a complication of surgery and pleural procedures such as thoracentesis or tube thoracostomy; presumably from unsterile technique.

BACTERIOLOGY

Published reports of PPEs have shown substantial variations in the bacteriology of isolated aerobes. It is likely that the introduction of antibiotics may have at least partially contributes to this variation. Over the years, the most commonly isolated organisms have varied between *Strep. pneumoniae, Strep. hemolyticus, Staph. aureus.*[19] In children, bacteriology is slightly different than in adults, *H. influenzae* being the most commonly isolated aerobe, the anaerobes being much less frequent.[20] Anaerobes require stringent transport process to preserve viability; the investigators with interest in culturing anaerobes have had greater success.[21]

Probably the most thorough bacteriological evaluation occurred during the Multicenter Intrapleural Sepsis Trial (MIST I); that evaluated the role of Streptokinase on a large number (454) patients, with complicated parapneumonic effusions.[22] Of the 434 patients who had pleural fluid cultures, 250 (58%) achieved a microbiological diagnosis using conventional methods.[23] In those with community-acquired infections, *Streptococcu*s was the commonest aerobe (52%), followed by *Staphylococcus* (10%), and gram-negative organisms (9%). Anaerobes were grown in 20% of the cases. Of hospital-acquired cases, the commonest aerobe was *Staphylococcus* (35%, nearly three quarter of which was methicillin-resistant) followed by gram-negative organisms (23%) and *Streptococcus* (18%).[23] Bacteriological diagnosis in 16% of the total samples was made by molecular diagnostic methods only.[23] In a quarter of the patients, organism could not be isolated. These results have implications for empiric therapy, and the choice of antibiotics. The important difference between the hospital and the community-acquired infections was that the predominant organism in the former was the *Staphylococcus*, and in the later the *Streptococcus;* a large fraction being *Methicillin-Resistant Staphylococcus aureus* (MRSA). The over all mortality was significantly higher in the hospital-acquired infections than in the community-acquired infections (Table 157.2).

TABLE 157.2: Description of the bacteriology of community and hospital-acquired pleural infection

Organism	*Community ascquired number (%)*	*Hospital acquired number (%)*
Aerobes		
Streptococcus	176 (52%)	11 (18%)
Streptococcus intermedius– anginosus–constellatus (“milleri”) group	80	4
Streptococcus pneumoniae	71	3
Streptococcus pyogens	9	0
Other *Streptococcus* species	16	4
Staphylococcus	35 (10%)	21 (35%)
S. aureus	27	6
Methicillin-resistant *S. aureus*	7	15
S. epidermidis	1	
Enterococcus spp.	4 (1%)	7 (12%)
Gram-negatives	29 (9%)	14 (23%)
Escherichia coli	11	2
Other coliforms	4	6
Proteus	6	2
Enterobacter spp.	5	1
Pseudomonas aeringosa	3	3
Anaerobes	67 (20%)	5 (8%)
Fusobacterium	19	1
Bacteroides	16	1
Peptostreptococcus	9	
Mixed anaerobes, unclassified	8	2
Prevotella spp.	13	1
Clostridium spp.	2	
Mycobacterium tuberculosis	2 (1%)	
Actinomyces spp.	4 (1%)	
Other*	17 (5%)	2 (3%)
Total	336	60

Both infections differ bacteriologically from pneumonia.

* Includes Burkholderia anthina, *Eikenella, Haemophilus influenzae,* Oral bacterium, *Pasteurella multocida, Klebsiella spp.*

Nick A Maskell, Sarah Batt, Emma L Hedley, et al. The Bacteriology of Pleural Infection by Genetic and Standard Methods and Its Mortality Significance. American Journal of Respiratory and Critical Care Medicine. 2006.[22]

CLINICAL FEATURES AND DIAGNOSIS

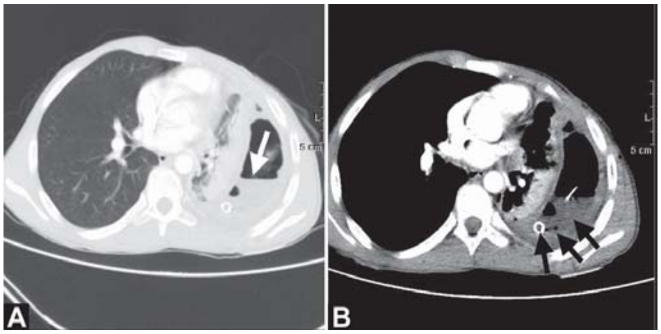
Patients with aerobic pleural infection usually present with features of pneumonia with an acute febrile illness, cough, purulent sputum and dyspnea. Pleuritic chest pain (due to parietal pleural involvement) is present in around 60% of patients. Absence of pain does not exclude the diagnosis of pleural infection.[1] Anaerobic infections present often in an indolent manner with weight loss, anorexia and malaise.[24]

There are no clinical criteria that could distinguish between pneumonia with or without PPE. Therefore, PPE should be considered while evaluating all patients with pneumonia, particularly those who are unresponsive to antimicrobial therapy. Further, not all patients with PPE have an acute illness.

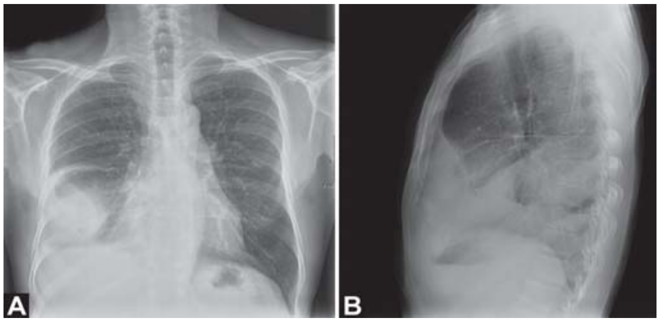
Radiological Investigations

Chest radiograph (PA view) (Figs 157.1A and B) can detect significant effusion and is often the only required imaging for its detection. Effusion may be free or loculated, may show evidence of air-fluid level. Empyema may give the appearance of pleural mass or tumor within the lung, when the collection occurs within a fissure. Computed Tomography (CT) scan of the chest is used to detect and quantitate minimal effusion. In resource limited settings like in India, blunting of the costophrenic angle on a lateral chest radiograph or obscuration of the dome of the diaphragm are considered sufficient to detect the presence of pleural fluid. Decubitus views may complement the information obtained from the erect chest radiographs.

In the lateral decubitus film, the amount of fluid can be roughly quantitated by measuring the distance between the chest wall and the lower part of the adjacent lung. If the length is less than 10 mm, the effusion is deemed to be too small to be clinically significant. Such effusions resolve with antibiotics alone.[1] CT evidence of pleural thickening is present in 80-100% of the empyemas (Figs 157.2A and B), so, its presence would favor this diagnosis, when PPE is being evaluated. “Split pleura sign” on contrast CT enhancement of visceral and parietal pleura differentiates empyema from a peripherally situated lung abscess[25, 26] (Fig. 157.3)



Figs 157.1A and B: CT thorax (left-lung window, right-mediastinal window) showing left sided loculated pleural effusion. Single arrow shows intercostal drainage tube; double arrow shows thickened and enhanced parietal pleura; triple arrow shows collapsed lung



Figs 157.2A and B: Chest radiograph PA and lateral views showing right sided loculated pleural effusion and fluid extending into the fissures

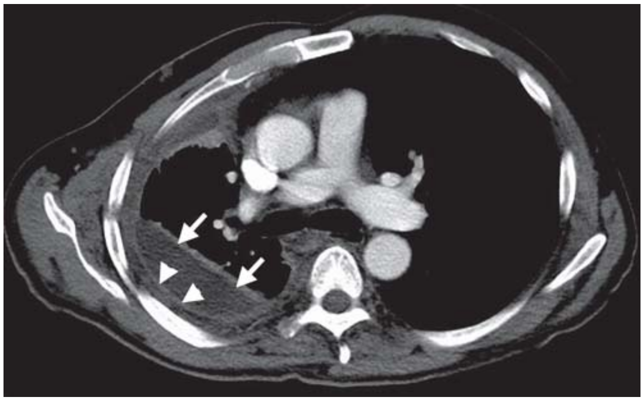


Fig. 157.3: CT thorax (mediastinal window) showing split-pleura sign. Arrow heads show thickened and enhanced parietal pleura and arrows show enhanced visceral pleura

Ultrasonography is an excellent method to assess pleural effusion. It can also help to quantify the amount of effusion by assessing the depth of fluid. It can also be used at the bedside for example in the Intensive Care Units (ICUs). Empyema results in dense echogenicity and loculations which are detectable on ultrasonogram. It is also helpful in ensuring successful pleural fluid aspiration in as high as 97% of the cases[27] (Fig. 157.4).

Thoracocentesis

Clinical features and routine blood tests are poor predictors of the need for drainage; the delay in instituting

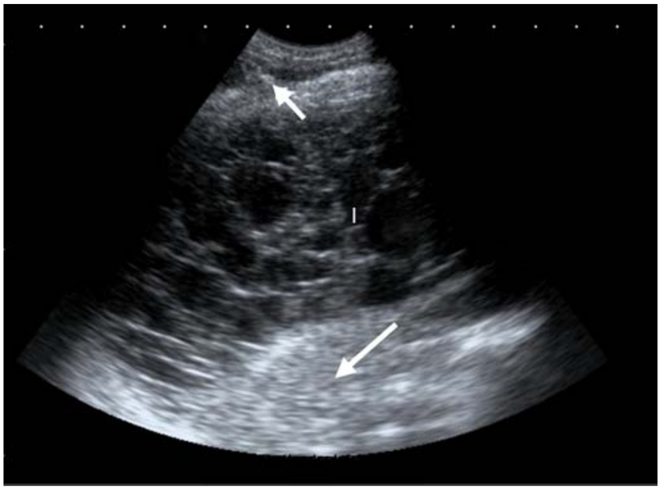

Fig. 157.4: Ultrasonogram chest showing multiple loculations. Short arrow indicates needle performing biopsy of the parietal pleura. Long arrow indicates collapsed lung

adequate drainage increases the morbidity. It is thus recommended that diagnostic pleural aspiration should be performed in all patients with PPE.[28] The exception to this rule is a small pleural effusion (<10 mm on a lateral decubitus chest radiograph), which may resolve with antibiotics alone.[29,30] When the effusion is small and does not completely cover the dome of the diaphragm in a chest radiograph (P-A view), it is safer to perform an ultrasound-guided aspiration. It is more accurate and reduces the patient discomfort.[31] The presence of frank pus on thoracentesis is diagnostic of empyema, no further tests are needed to confirm the diagnosis. If not, the pleural fluid should be sent for microbiological and biochemical studies. Pus from empyema is also sent for microbiological cultures to aid in the choice of antibiotics. Tuberculous etiology should always be kept in mind while evaluating empyma in high TB prevalence settings. It is our practice to perform closed pleural biopsy in all patients with exudative effusions or empyema, unless the effusion is of acute onset and preceded by a documented pneumonia. The biopsy yield in tuberculosis is higher than the pleural fluid smears, when positive it aids in prompt commencement of anti-TB treatment.

PLEURAL FLUID ANALYSIS

In paraneumonic effusion, the fluid may vary between clear or straw colored and odorless to thick, purulent and foul smelling. Only around 11% of effusions exhibit foul smell.[32] Foul odor could indicate an anaerobic or mixed (aerobic and anaerobic) etiology. Absence of foul smell however does not rule out an anaerobic infection.[32, 33] After gross examination, the pleural fluid is tested for proteins, LDH, glucose and pH. Another sample is sent for microbiological studies—Gram stain, aerobic cultures, mycobacterial and fungal cultures, as deemed necessary. If the resources permit, anaerobic cultures too should be done on all exudative effusions of undetermined etiology. In countries, like India, with a high prevalence of tuberculosis, AFB smears and mycobacterial cultures are also important. The pleural fluid from PPEs and empyemas is an exudate; presence of a transudate on the basis of the light's criteria suggests an alternative diagnosis. The presence of a predominance of lymphocytes should raise the possibility of malignancy or tuberculosis. Fluid drainage is imperative in the presence of purulence of fluid. In the absence of purulent fluid and of positive microbiology, biochemical markers are used as surrogates for evidence of active pleural infection.

It is well understood that PPE with an acidic pH (< 7.20) is more likely to run a complicated course with loculated fluid collections and empyema when compared to an effusion with pH greater than 7.20. Intercostal drainage is instituted to avert this complication, antibiotic treatment alone may not suffice.[29,34] Furthermore, there is more likelihood of the need for surgical intervention in those with an acidic pH (< 7.20).

Several investigators have looked at the evidence for the use of biochemical markers.[35] Pleural fluid pH emerged as the best predictor of a complicated course in a meta-analysis that critically assessed the markers to separate effusions that were likely to run a simple course from those that were likely to run a complicated course (i.e. became frankly purulent, nonpurulent fluid requiring drainage and nonpurulent fluid progressing to frank pus later in the clinical course or at autopsy).[36] The pleural fluid glucose and LDH did not improve the diagnostic accuracy, reliance on these values (glucose <35 mg/dL and LDH >1000) is recommended only when accurate pH values not available. More recently, these findings have been confirmed; the pleural fluid pH had the highest accuracy followed by pleural fluid glucose and LDH and pleural fluid volume.[37] Poor prognostic and other factors that distinguished complicated from uncomplicated PPE could be summarized as pH less than or equal to 7.2, pleural fluid glucose less than or equal to 60 mg/dL and pleural fluid LDH greater than or equal to 3 times upper limit for serum. Current guidelines do not recommend institution of tube drainage in effusions with pH of greater than 7.20 (Table 157.3).[30,35] If there is no response to antibiotic treatment, repeat pH

TABLE 157.3: Categorizing risk for poor outcome in patients with PPE

	Pleural space anatomy			*Pleural fluid bacteriology*			*Pleural fluid chemistry**	*Category*	*Risk of poor outcome*	*Drainage*
A_0	Minimal, free-flowing effusion (<10 mm on lateral decubitus)[†]	AND	B_x	Culture and Gram stain results unknown	AND	C_x	pH unknown	1	Very low	No[‡]
A_1	Small-to-moderate free-flowing effusion (>10 mm and <½ hemithorax)	AND	B_0	Negative culture and Gram stain[§]	AND	C_0	pH ≥7.20	2	Low	No[‖]
A_2	Large, free-flowing effusion (>½ hemithorax)[¶] loculated effusion,[#] or effusion with thickened parietal pleura**	OR	B_1	Positive culture or Gram stain	OR	C_1	pH <7.20	3	Moderate	Yes
			B_2	Pus				4	High	Yes

*pH is the preferred pleural fluid chemistry test, and it must be determined using a blood gas analyzer. If a blood gas analyzer is not available, pleural fluid glucose should be used (P_0 glucose $ 60 mg/dL; P_1 glucose, 60 mg/dL). The panel cautions that the clinical utility and decision thresholds for pH and glucose have not been well-established.

[†] Clinical experience indicates that effusions of this size do not require thoracentesis for evaluation, but will resolve.

[‡] If thoracentesis were performed in a patient with A_0 category pleural anatomy and P_1 or B_1 status found, clinical experience suggests that the P_1 or B_1 findings might be a false-positive. Repeat thoracentesis should be considered if effusion enlarges and/or clinical condition deteriorates.

[§] Regardless of prior use of antibiotics.

[‖] If clinical condition deteriorates, repeat thoracentesis and drainage should be considered.

[¶] Larger effusions are more resistant to effective drainage, possibly because of the increased likelihood that large effusions will also be loculated.

#Pleural loculations suggest a worse prognosis.

**Thickened parietal pleura on contrast-enhanced CT suggest presence of empyema.

(Gene L Colice, Anne Curtis, Jean Deslauriers, et al. Medical and surgical treatment of parapneumonic effusions: An evidence-based guideline.[30] Chest. 2000; 118:1158-71 with permission)

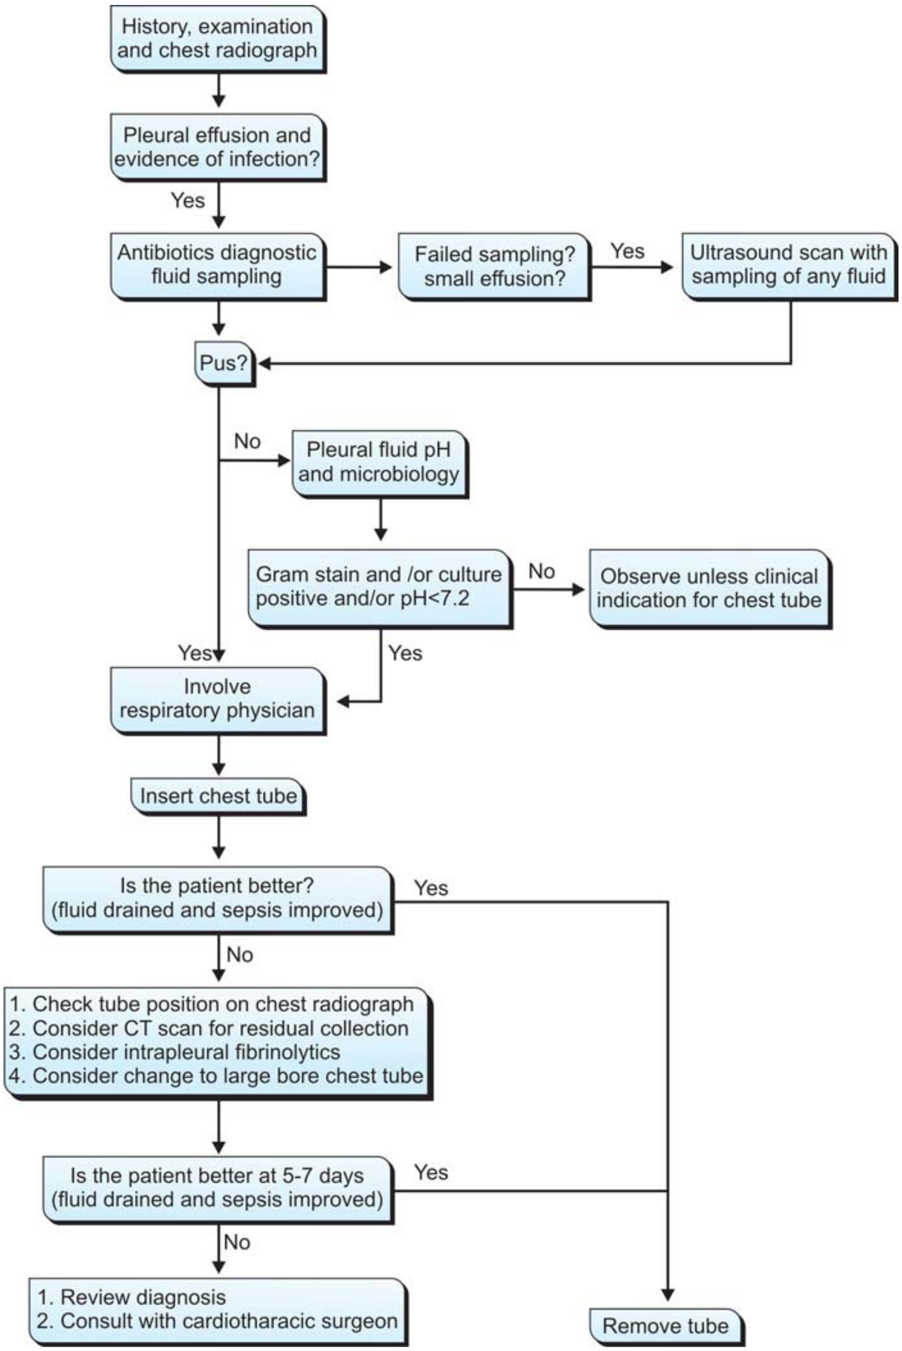
measurement is recommended.[28] The presence of bacteria demonstrated by smear or culture of pleural fluid should merit treatment with intercostal drainage regardless of pleural fluid pH.

False positive acidic pH measurement can be seen in malignant effusion, tuberculosis, rheumatoid and lupus pleuritis. Since pleural fluid pH is crucial to decision making, the fluid should be collected in a heparinized syringe, without contamination with lignocaine (which is acidic), and analyzed immediately using a blood gas analyzer.[38] Other methods of measuring pH, such as using litmus paper, have been shown to be unreliable.[39] Measurement of pH should not be performed on obviously purulent pleural fluid; it may damage the blood gas analyzer. Moreover, tube drainage should be instituted regardless of the pH value in case of purulent effusion.

The PPE caused by *Proteus* is known to present paradoxically with alkalotic pleural fluid pH, because the proteus split urea to produce ammonia.[40] Recent studies have evaluated the possible role of markers for complicated PPEs. For example, TNF-α using a cut off of greater than 80 µg/ml and polymorphonuclear elastase (PMN-E) at a cut off of greater than 3,500 µg/ml have shown a good sensitivity and specificity.[41-43]

TREATMENT

Prompt recognition is essential for optimal management of pleural infection. Antibiotic therapy and drainage of



History, examination and chest radiograph
Pleural effusion and evidence of infection?
Yes
Antibiotics diagnostic fluid sampling
Failed sampling? small effusion?
Yes
Ultrasound scan with sampling of any fluid
Pus?
No
Pleural fluid pH and microbiology
Gram stain and /or culture positive and/or pH<7.2
No
Observe unless clinical indication for chest tube
Yes
Yes
Involve respiratory physician
Insert chest tube
Is the patient better? (fluid drained and sepsis improved)
Yes
No
1. Check tube position on chest radiograph
2. Consider CT scan for residual collection
3. Consider intrapleural fibrinolytics
4. Consider change to large bore chest tube
Is the patient better at 5-7 days (fluid drained and sepsis improved)
Yes
No
1. Review diagnosis
2. Consult with cardiotharacic surgeon
Remove tube

Fig. 157.5: Diagnostic algorithm for the management of patients with pleural infection.[35] (Davies CWH, Gleeson FV, Davies RJO. BTS guidelines for the management of pleural infection. Thorax. 2003; 58(Suppl II):ii18-ii28 with permission

fluid collection constitute the cornerstone of management. The British Thoracic Society has drawn an excellent algorithm for the management of patients with pleural infection (Fig. 157.5).

Antibiotic Treatment

All patients suspected of having pleural infection need treatment with antibiotics.[35] While it is ideal to prescribe antibiotics based on the results of pleural and/or blood cultures, this causes a delay in the commencement of treatment. Therefore, appropriate "empiric" antibiotic treatment should commence for all patients. Selection of antibiotics should be based on Gram stain results, presence of hospital acquired versus community acquired infection and on the clinical severity of the illness. Antibiotic penetration into the pleural space is variable in the descending order from metronidazole, penicillin, clindamycin, vancomycin, ceftriaxone to gentamycin and other aminoglycosides.[44] Other studies showed that quinolones and clarithromycin had good penetration into the pleural space.[45, 46]

Cultures do not always grow pathogens, but may remain negative in up to 42% of the cases.[23] In community-acquired infection, the likely organisms include *Streptococcus milleri, Streptococcus pneumoniae,* staphylococci, and *Haemophilus infiuenzae.* Although the *S. milleri* group is highly sensitive, a substantial proportion of the others are resistant to β-lactams.[47] "Atypical" bacteria constitute an exceedingly rare cause of pleural infection, although they can cause a simple PPE, anaerobic infection occurs in approximately 10%.[48] When cultures are negative, antibiotics should cover community acquired or hospital acquired pathogens as the case may be, anaerobes should be covered too. Antibiotic choice should be directed by local policy guided by standard international and national recommendations one such guideline is provided (Table 157.4).

Empirical antibiotic regimen should be rationalized once culture results become available. Given the difficulty in culturing anaerobic organisms, continuation of anti-anaerobic therapy is usually necessary. Direct data do not exist on how long to treat empyema. Most physicians continue antibiotic treatment for at least 3 weeks, with at least 1 week of intravenous antibiotics. Support for this recommendation comes mostly from the experience in treatment of lung parenchymal abscesses.[47]

Closed Intercostal Drainage

Open drainage as a treatment for infected pleural effusions was established since the time of Hippocrates, and this practice continued till the influenza epidemic of 1917-19, when the closed-tube drainage was first introduced.[49] There is consensus of opinion regarding the need of pleural space drainage under the following circumstances:

- Frank pus or turbid/cloudy fluid within the pleural space[30, 35]
- Presence of organisms identified by gram stain or culture from (non-purulent) effusion
- Effusion fluid with a pH less than 7.2
- Large uncomplicated effusions for relief of dyspnea.

Repeated thoracentesis is an alternative, albeit a less popular strategy compared to intercostal drain insertion. It facilitates increased mobility and lower complication, in particular infection rates. This management strategy has support from experimental and clinical trials.[50-52] However, there is no randomized trial that has compared this approach with tube drainage.

Many experienced clinicians believe that a large-bore chest drain (>20 French) is necessary to treat empyema. However, studies with smaller bore catheters (11-14 French) have shown equal success.[31,53-56] CT or ultrasound guided insertion of drain may be more optimal for an appropriate placement of the tube. In loculated effusions, the tube can be placed under guidance into the biggest locula. The role of suctioning and flushing the drainage tube with around 30 ml of

TABLE 157.4: Illustrative antibiotic regimens for the initial treatment of culture negative pleural infection

Origin of infection	*Intravenous antibiotic treatment*	*Oral antibiotic treatment*
Community acquired culture negative pleural infection	Cefuroxime 1.5 g tds IV + Metronidazole 400 mg tds orally or 500 mg tds IV Benzyl penicillin 1.2 g qds IV + Ciprofloxacin 400 mg bd IV Meropenem 1 g tds IV + Metronidazole 400 mg tds orally or 500 mg tds IV	Amoxycillin 1 g tds + Clavulanic acid 125 mg tds Amoxycillin 1 g tds + Metronidazole 400 mg tds Clindamycin 300 mg qds
Hospital acquired culture negative pleural infection	Piperacillin + Tazobactam 4.5 g qds IV Ceftazidime 2 g tds IV Meropenem 1 g tds IV ± Metronidazole 400 mg tds orally or 500 mg tds IV	Not applicable

No particular regimen is the single "ideal" choice. Drug doses should be appropriately adjusted in the presence of renal or hepatic failure. CWH Davies, FV Gleeson, RJO Davies. BTS guidelines for the management of pleural infection. Thorax. 2003; 58 (Suppl II):ii18-ii28[35] with permission sterile saline four times daily can be helpful, particularly when a small bore chest tube is used. The optimal timing of drain removal is unknown, although clinical response is clearly the most important parameter. It is our practice to remove the drainage tube, when the drainage is less than 50 ml; provided the fluid is clear and non-turbid. If on the other hand the fluid is turbid, we remove it only after the drainage reduces to less than 10 ml. If there is inadequate drainage or failure of resolution with a single chest drain, there may be a need to re-position the tube after radiological assessment or placement of additional tubes. Failure of chest tube drainage heralds increased morbidity and mortality.[57]

Intrapleural Fibrinolytics

Loculated pleural collections pose challenge in the treatment, by hampering efforts at drainage which can also lead to failure of "medical treatment". Instillation of intrapleural fibrinolytics has been practiced for more than 50 years.[58] Over the years, streptokinase, streptodornase, urokinase and tPA have been used to break fibrin adhesions and facilitate drainage.

The apparent benefit of fibrinolytics was supported by five randomized studies in adults which showed success rates between 60% and 95%.[59-62] Although fibrinolytics conferred benefits, such as decreased hospital stay, improved radiographic appearance and decreased rate of surgery, the benefits were variable and inconsistent.[63] Thus, doubts began to arise about the unequivocal benefits of fibrinolytics in pleural infection. Subsequently, the MIST 1 study, a large trial across 52 UK hospitals; showed no difference between intrapleural streptokinase and saline.[22] The routine use of fibrinolytic agents at this point is not supported by evidence. Nevertheless, intrapleural fibrinolytics probably aid in thoracic decompression in the case of large infected pleural collections and alleviate respiratory embarrassment in this situation.[22] The dosage schedule for instillation of streptokinase is 250 000 units (once or twice daily for 3 days) and for urokinase, 100 000 units (once daily for 3 days).

Surgical Treatment

Medical therapy fails in up to 30% of patients with empyema.[22,64] No good-quality data exists on the optimum timing of surgery and indications for reference.[35] Patients who do not improve clinically and radiologically after 7 days of standard treatment, can derive benefit from surgical interventions.[35,57] The Video-Assisted Thoracic Surgery (VATS) is the possible next step in the treatment of empyema when tube drainage has failed. The adhesions and septae can be divided to aid drainage, although this may need to be done early.[65] More recent series report higher success rates with VATS.[66,67] There are no randomized trials comparing VATS with thoracotomy, its role in the treatment of early disease as well as in chronic empyema is yet to be defined.[68] The outcome of thoracotomy and decortication is generally good, with success rates of up to 95% in this highly selected group, with significant associated complications.[64,69] Rib resection and open surgical drainage under local anesthesia are possible in patients who are unfit for general anesthesia.

Decortication is likely the only treatment option in cases of chronic empyema with persistent sepsis and pleural fibrosis.[70]

Nutrition

Patients with empyema enter a catabolic state; hence, good nutrition is vital. It has been observed that patients with low serum albumin have a worse outcome from empyema.[71] Although no trial has addressed this issue, an aggressive nutritional support is important for the patients.

Pneumothorax

Uma Devaraj, George D'Souza

INTRODUCTION

A pneumothorax is air in the pleural space. Pneumothoraces can be classified as "spontaneous", which occur without antecedent trauma or other obvious cause, and "traumatic", which occur from direct or indirect trauma to the chest (Fig. 158.1).

Traumatic pneumothorax is further subcategorized as "iatrogenic", which is a consequence of a diagnostic or therapeutic maneuver. Spontaneous pneumothoraces are subdivided into primary (PSP) and secondary (SSP) spontaneous pneumothoraces. Primary spontaneous pneumothoraces occur in otherwise healthy individuals, though many have occult lung disease as evidenced by subpleural blebs on Computed Tomography (CT) scans. Secondary spontaneous pneumothoraces occur as a complication of underlying lung disease.

Some Definitions

Recurrent pneumothorax: A recurrent pneumothorax is one that occurs on the same side after seven days of the initial resolution. A pneumothorax is considered "persistent" if the air leak lasts for more than five days.

Closed pneumothorax: A closed pneumothorax[1] is one in which the alveolar pleural communication is sealed. The degree to which the lung collapses depends on the volume of air introduced during the air leak.

Tension pneumothorax: The intrapleural pressure rises in proportion to the volume of air in the pleural cavity and when it is above atmospheric pressure, it is called tension pneumothorax.

Open pneumothorax: An open pneumothorax[1] communicates with the atmosphere and results in pendulum breathing (shunting of the physiological dead space between the two lungs) in addition to lung collapse.

Pathophysiology

Normally, the pressure in the pleural space is negative with reference to the atmospheric pressure during the entire respiratory cycle. The negative pressure is due to the inherent tendency of the lungs to collapse and of the chest wall to expand. The resting volume of the lung, the Functional Residual Capacity (FRC), is the volume at which the outward pull of the chest wall is equal, but opposite in direction, to the inward pull of the lung with the respiratory muscles relaxed. Pneumothorax causes alterations of lung volumes and mechanics; for example on FRC as shown in Fig. 158.2.

The negative intrapleural pressure is not uniform throughout the pleural space; a gradient of 0.25 cm of water per centimeter exists from the base to the apex of the lung. This result in greater distension of the alveoli at the apex as the pressure is more negative at the apex. This makes the apex vulnerable due to greater swings in pressure during a respiratory cycle.

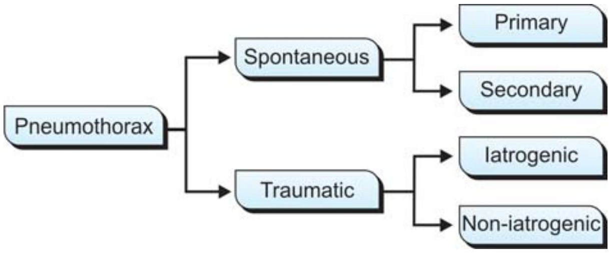

Fig. 158.1: Classification of pneumothorax

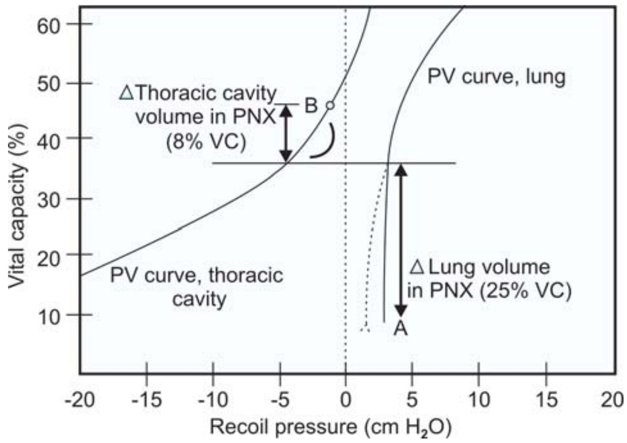

Fig. 158.2: Influence of pneumothorax on the volumes of the lung and hemithorax. In this illustration, the pneumothorax has caused the intrapleural pressure to rise from -5 to -2.5 cm H_2O. The change in lung and thoracic cavity volumes depends on their respective pressure volume curves [(dashed lines) to new volumes for the lung (A) and thoracic cavity (B)]. The volume of the hemithorax becomes larger by 8% for a fall in lung volume by 25% of VC because of the difference in slopes of the two pressure volume (PV) curves.
PNX, Pneumothorax[2]

A bleb is a gas-containing space within the visceral pleura and is usually seen at the apex. A bulla is a space lined partly by thickened fibrotic pleura and partly by fibrous tissue within the lung itself.[3] Air reaches the pleural space either due to rupture of a subpleural bulla or bleb, rupture of overdistended alveoli into the adjacent bronchovascular sheath medially to produce pneumomediastinum, which may be accompanied by subcutaneous emphysema or pneumothorax, or rupture of overdistended alveoli that can dissect air from alveoli to the peripheral portion of the lung.

The pleural pressure is always less than the alveolar pressure and the atmospheric pressure owing to the elastic recoil of the lung. Therefore, if a communication develops between the pleural space and an alveolus or between the pleural space and the atmosphere, air will flow into the pleural space until a pressure gradient no longer exists or until the communication is sealed.

At FRC, the thoracic cavity is below its resting volume and the lung is above its resting volume. Hence with a pneumothorax, the thoracic cavity enlarges and the lung becomes smaller. This results in the main physiologic consequences of decreased vital capacity and arterial PO_2. The reduction in arterial PO_2 appears to be caused by areas with low ventilation-perfusion ratios, anatomic shunts and occasionally, alveolar hypoventilation.[4] The decreased vital capacity is usually well tolerated in patients with PSP whereas it can precipitate respiratory failure in patients with SSP. The total lung capacity, functional residual capacity and diffusing capacity are also reduced, although less than the vital capacity.[3] When perfusion to the collapsed lung is preserved, there is an increase in pulmonary shunt and substantial hypoxemia. If perfusion to the collapsed lung is reduced by hypoxic vasoconstriction, hypoxemia may be minimal. In general, pneumothoraces occupying less than 25% of the hemithorax are not usually associated with significant shunts. Redistribution of pulmonary blood flow results in improvement of hypoxemia within 24 hours, despite the extent of the pneumothorax in most circumstances.

Resolution of Pneumothorax

Normally, there is no air in the pleural space as the sum of all the partial pressures in the capillary blood with a person breathing room air is about 706 mm Hg (PN_2 + PO_2 + PH_2O + PCO_2 =573 + 40 + 47 + 46 = 706) which is less than atmospheric pressure. When there is air, it is reabsorbed from the pleural space by simple diffusion into the venous blood. The rate of gas resorption depends on the following:

1. The pressure gradient for the gases between the pleural space in relation to the venous blood
2. The diffusion properties for the gases present in the pleural space
3. The area of contact between the pleural gas and pleura
4. The permeability of the pleural surface (i.e. fibrotic pleura absorbs less than a normal pleura)

The net gradient for gas absorption, from pleural space into capillary blood, is only 54 mm Hg (760 to 706) on assuming that the pleural pressure is approximately zero when there is a pneumothorax. If the patient is given 100% oxygen, the sum of all the partial pressures in the capillary blood will probably fall below 200 mm Hg (the PN_2 will approach zero, whereas the PO_2 will remain under 100 mm Hg; PN_2 + PO_2 + PH_2O + PCO_2 = 0 + 100 + 47 + 46 = 193). Therefore, the net gradient for gas absorption will exceed 550 mm Hg or be 10 times greater than it was with the patient breathing room air. The solubility and diffusion properties of different gases vary considerably and the speed of reabsorption depends on the type of gas. Oxygen is absorbed 62 times faster than nitrogen, the slowest gas to be reabsorbed. Carbon dioxide is absorbed 23 times faster than oxygen, and carbon dioxide and water vapor equilibrate almost instantaneously. This can be made use of to hasten the absorption of a pneumothorax, by making the patient breathe 100% oxygen.

PRIMARY SPONTANEOUS PNEUMOTHORAX

Primary Spontaneous Pneumothorax (PSP) occurs more commonly in men between ages of 20–40 years of age. Women tend to develop PSP, 2–5 years earlier than men though they have a much lower incidence with a male: female ratio of 2.5:1.[3]

Incidence

The incidence of PSP reported in the Western literature is 7.4–18 cases/1,00,000 population per year in males and 1.2–6 cases/1,00,000 population per year in females (age-adjusted incidence).[5] The reported incidence of PSP among all patients presenting with spontaneous pneumothorax have been widely variable in the few studies available from India and has ranged from 12.5 to 64%.[6] The annual incidence for primary and secondary spontaneous pneumothorax are 20.0 and 80.0 per 1,00,000 hospital admissions, respectively.[6] This figure probably overestimates the true incidence of SP in the general population, since the study is hospital based with the denominator being all hospitalized patients.

Etiology

Though PSP by definition occurs in people without underlying lung disease, most often it is associated with the rupture of subpleural blebs or bullae on the apical portion of the upper lobes. Blebs can be found in more than 75% of patients undergoing thoracoscopy for treatment of PSP. It is however unclear how often these lesions are actually the site of air leakage. Fluorescein-Enhanced Autofluorescence Thoracoscopy (FEAT), a novel method involving an administration of fluorescein aerosol administration, followed by sequential white light and blue light thoracoscopy using a blue light, shows FEAT-positive lesions that are normal when viewed under normal White-light Thoracoscopy (WLT).[7] Several areas of subpleural fluorescein accumulation, undetectable by normal WLT, were observed. This observation supported the concept that air leakage in PSP is not necessarily associated with, or located at blebs or bullae, but can occur at areas that have a completely normal appearance during WLT.

Only in a small number, blebs are ruptured at the time of thoracoscopy or surgery. In the remaining, other lesions are present, called “pleural porosity”; these are areas of disrupted mesothelial cells at the visceral pleura, replaced by an inflammatory elastofibrotic layer with increased porosity, allowing air to leak into the pleural space.

The development of blebs, bullae and areas of pleural porosity may be linked to a variety of factors. These include distal airway inflammation, hereditary predisposition, anatomical abnormalities of the bronchial tree, ectomorphic physiognomy with the more negative intrapleural pressures and the relative apical ischemia, low body mass index and caloric restriction and abnormal connective tissue.

There is a significantly increased risk of spontaneous pneumothorax in smokers. When four separate series of patients with PSP were combined, (461 of 505 patients) 91% with PSP were smokers or ex-smokers. The occurrence of a spontaneous pneumothorax is related to the level of cigarette smoking. In men there appears to be a dose effect with the relative risk of a pneumothorax, seven times higher in light smokers (1–12 cigarettes/day), 21 times higher in moderate smokers (13–22 cigarettes/day) and 102 times higher in heavy smokers (>22 cigarettes/day) than in nonsmokers.[8]

Patients with PSP tend to be taller and thinner than control subjects. A study on military recruits who developed spontaneous pneumothorax found that they were, on average, 2 inches taller and 25 pounds lighter than the typical military recruit.[2] As pleural pressure drops by 0.20 cm of H_2O per cm of vertical height, pleural pressure is more negative at the apex of lung in tall people; therefore the alveoli at their lung apex are subjected to a greater mean distending pressure. In the long run, this could lead to the formation of subpleural blebs in those tall people who are genetically predisposed to bleb formation.

In women, smoking and body shape appear to be less relevant than in men. Catamenial pneumothorax is seen in about 3% of PSP in women.[9] There are few reports (56 so far) of pneumothorax in pregnancy.[10] Another cause exclusive to females is lymphangioleiomyomatosis.

Genetics

Various studies have shown an important genetic contribution in the development of spontaneous pneumothorax. Some cases are due to an autosomal dominant gene[11] with incomplete penetrance, the penetrance being lower in women (21%) than in men (50%). There also appears to be an inheritance due to an X-linked recessive gene.[12]

Birt-Hogg-Dubé syndrome (BHD) is an autosomal dominant condition characterized by the presence of facial fibrofolliculomas and pulmonary cysts which may be associated with spontaneous pneumothorax and renal tumors. BHD is caused by loss of functional mutations in the folliculin (FLCN) protein.[13] The molecular function of

FLCN is still largely unknown and debated. There is opposite and conflicting evidence of the role of FLCN in mammalian target of rapamycin signaling/phosphorylated ribosomal protein S6 (p-S6) activation.

Other genetic conditions associated with spontaneous pneumothorax are lymphangioleiomyomatosis,[14] alpha-1 antitrypsin deficiency[15] and cystic fibrosis.[16] Pneumothorax also occurs with increased frequencies with Marfan syndrome,[17] Ehlers-Danlos syndrome[18] and homocystinuria.[19]

Clinical Manifestations

PSP occurs most commonly between 20 and 40 years, and rarely after 40 years. Most often PSP occurs during rest rather than exertion. The main symptoms are chest pain and dyspnea. Chest pain is acute in onset, pleuritic in nature and localized to the side of pneumothorax. Though onset is acute, there is a delay in seeking medical attention as the symptoms subside in the next 24 hours. In one series, 18% of patients waited more than one week after development of symptoms before seeking medical help. Other uncommon manifestations due to a pneumothorax are cough, hemoptysis, orthopnea and Horner's syndrome.[3]

The physical findings depend on the size of the pneumothorax; small pneumothoraces (occupying less than 20%) may have normal physical findings. In PSP, the vital signs are usually normal, except for moderate tachycardia. A tension pneumothorax should be suspected if the pulse rate exceeds 140 beats/minute, or if hypotension, cyanosis or electromechanical dissociation is present.

On examination of the chest, the ipsilateral hemithorax is larger and has reduced respiratory movements than the contralateral side. On the affected side, tactile fremitus is absent, the percussion note is hyperresonant and the breath sounds are absent or reduced. The lower edge of the liver may be shifted inferiorly with a right-sided pneumothorax. With a large pneumothorax, the trachea may be shifted toward the contralateral side. Hamman's sign which is a crunching or clicking noise heard synchronous with the heartbeat, may be auscultated with a pneumothorax (particularly on the left side) or pneumomediastinum and is influenced by respiration and body position.[20]

Lab Investigations and Diagnosis

Diagnosis can be confirmed in the majority of cases with an upright posteroanterior chest radiograph demonstrating a pleural line. Chest radiograph shows collection of lucent gas, with absent pulmonary vascular markings, between the outer margin of visceral pleura (lung) and parietal pleura (chest wall) (Fig. 158.3). Expiratory radiographs add little and are not recommended in diagnosis of pneumothorax any longer.[21] The lateral decubitus radiograph is superior to erect or supine chest radiograph and is as sensitive as CT scanning in pneumothorax detection.

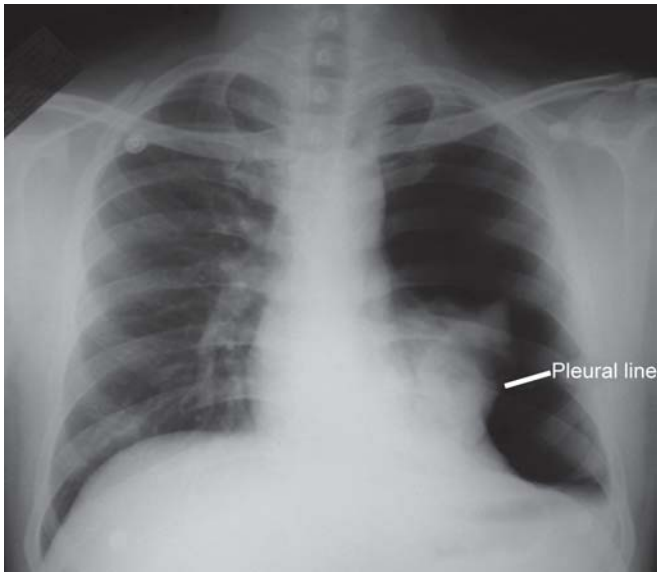

Fig. 158.3: Chest radiograph showing left sided pneumothorax

Quantifying a Pneumothorax

There are many ways to calculate the size of the pneumothorax:

Light Index

The degree of collapse (PNX %) can be measured by taking the average diameters of the lung and the hemithorax (Fig. 158.4), cubing these diameters and using the following equation, PNX% =100 [1-(lung diameter^3/hemithorax diameter^3)]. As lung collapses asymmetrically in a pneumothorax, computed tomography best predicts the light index.[2]

Collins et al. have described an alternate method for estimating the percentage of collapse.[22] With their method, the distance between the apex of the partially collapsed lung and the apex of the thoracic cavity (distance A), and the midpoints of the upper (distance B) and lower (distance C) halves of the collapsed lung and the lateral chest wall are measured in centimeters (Fig. 158.5). The percentage of the pneumothorax can be calculated by the formula: % PNX=4.2+ [4.7-(A+B+C)]

When the volume calculated from a helical CT scan was compared with the volume measured with this

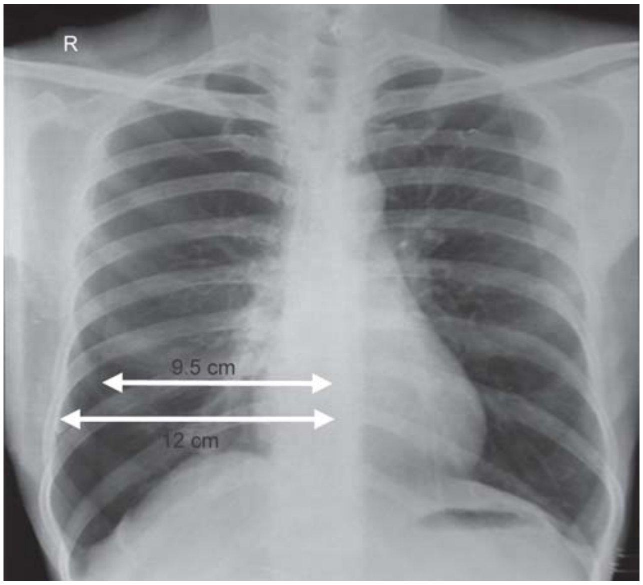

Fig. 158.4: Quantitation of pneumothorax by light index: 100 $(12^3 - 9.5^3/12^3)$

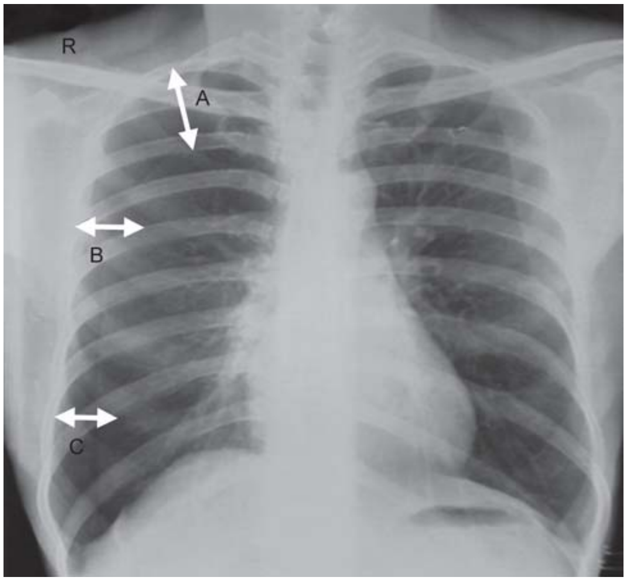

Fig. 158.5: Alternative formula for quantitation of pneumothorax by Collin et al.

formula in 20 patients, the correlation coefficient was 0.98. However the British Thoracic Society prefers to group pneumothoraces into "small" or "large" depending on the presence of a visible rim of <2 cm or ≥2 cm between lung margin and the chest wall.[21] This is a more practical way of calculating the size of a pneumothorax for therapeutic purposes.

Thin walled cysts or avascular bullae can be mistaken for pneumothorax. Skin fold, clothing, tubing, or chest wall artifacts are other artifactuals which can mimic pneumothorax on the chest radiograph. In patients with severe bullous lung disease, computed tomography scan should be done and will help to differentiate emphysematous bullae from pneumothoraces and save the patient unnecessary and potentially dangerous aspiration (Fig. 158.6). Computed Tomography scans are useful in critically ill patients when upright or decubitus films are not possible and in detecting small pneumothoraces not evident on the chest radiograph.

Pleural effusions may accompany a pneumothorax in 20 to 25% of cases. A hemo-pneumothorax occurs in 2 to 3% of spontaneous pneumothoraces. This is due to bleeding from rupture or tearing of vascular adhesions between the visceral and parietal pleura as the lung collapses.

Electrocardiographic changes may be seen due to mechanical effects of a pneumothorax. A left sided pneumothorax may mimic anterolateral myocardial infarction showing rightward shift of the frontal QRS axis, diminution of precordial R voltage, decrease in QRS amplitude, and precordial T-wave inversion.[23] Absence of significant Q wave and ST segment elevation helps differentiate ECG changes due to pneumothorax from that due to myocardial infarction. With a right sided pneumothorax, the changes mimicking a posterior myocardial infarction may be seen like diminution of precordial QRS voltage, right-axis deviation and a prominent R wave in lead V_2 with associated loss of S-wave voltage.

Arterial blood gas analysis is frequently abnormal in patients with pneumothorax with the PO_2 being less than 80 mm Hg in 75% of patients.[21]

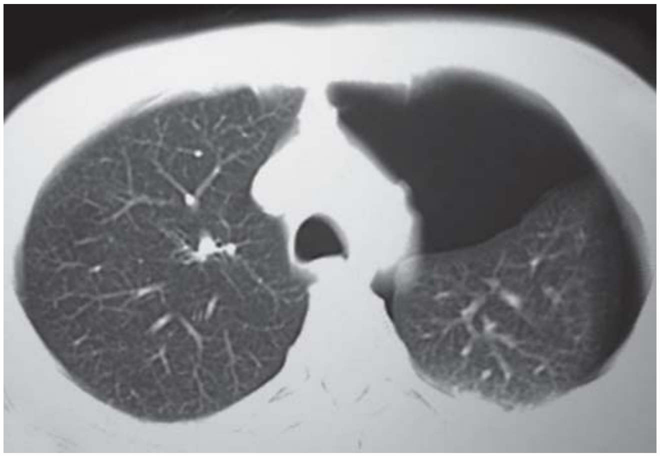

Fig. 158.6: Chest CT scan showing left pneumothorax

Recurrence Rates

There is a risk of recurrence, particularly soon after the initial episode. Sadikot et al. followed 153 patients with PSP for a mean of 54 months and reported a 39% recurrence rate on the ipsilateral side, the majority within the first year.[24] Once a patient has a PSP, there is also an increased risk of having a pneumothorax on the contralateral side. In the same study, Sadikot et al. showed that 15% of the 153 patients developed a pneumothorax on the contralateral side. The rate of recurrence increases with each successive pneumothorax. Thus there is a recurrence in a third of patients after the first PSP, but this may increase to 62% after a first recurrence and to 83% after a third.

Treatment

The main goals of therapy are to clear the air from the pleural space and to prevent recurrence. A multitude of therapeutic options are available for treatment of PSP, varying from observation to surgery (Table 158.1). An algorithmic approach can be employed for management (Fig. 158.7).

Observation

This is generally reserved for asymptomatic patients with a small pneumothorax (less than 20%). This is based on the fact that once the communication between the alveoli and the pleural space is sealed, the pleural space air is gradually reabsorbed. Rate of spontaneous reabsorption is slow. Kircher and Swartzel[23] estimated that 1.25% of the volume of the hemithorax is absorbed every 24 hours. Therefore, if a patient has a 20% pneumothorax, it will take roughly 16 days for pleural air to be absorbed spontaneously.

A patient presenting with a first episode and a small (i.e. only partial, usually apical) pneumothorax should not be treated, but can safely be discharged and followed on an outpatient basis.

TABLE 158.1: Treatment options for PSP

- Video-assisted thoracoscopic surgery (VATS) with blebectomy or bullectomy
- VATS with pleural abrasion or partial pleurectomy
- Axillary thoracotomy

Supplemental Oxygen

The administration of supplemental oxygen accelerates the rate of pleural air absorption. Chernick and Avery[25] demonstrated that the administration of humidified 100% oxygen to rabbits with experimentally induced pneumothoraces increased the rate of absorption six fold. Subsequent studies in patients with a spontaneous pneumothorax have demonstrated that pleural air is absorbed about four times faster when the patients are given high concentrations of supplemental oxygen to breathe.[26] Supplemental oxygen at high concentrations is recommended in hospitalized patients with any type of pneumothorax who are not subjected to aspiration or tube thoracostomy.

Simple Aspiration

There is now sufficient evidence that simple manual aspiration should be the first-line treatment approach in these PSP patients.[27,28] The success rates vary between 50 and 80% of cases, averaging two third of cases. Complications are absent; pain and discomfort are minimized and recurrence rates are similar to those seen after typical chest tube drainage. It can be done in the outpatient with immediate discharge in over half the cases and the length of stay, when necessary, is significantly shortened. Patients residing more than 15 minutes from the hospital should be considered for overnight observation in the hospital. Patients should be followed up in 24–72 with a chest radiograph.

PSP recurrence prevention should only be proposed after a first recurrence because thereafter the rate of recurrence increases with each successive pneumothorax. Exceptions are patients at professional risk (aviation personnel, divers) and when a prolonged air leak (14 days) is present. Anxious patients are a relative indication. Intrapleural insertion of a catheter or tube has only a minimal (if any) effect on prevention of recurrence (34 to 36% observed recurrence rates after chest tube drainage only).[21]

Procedure

A 16- or 18-gauge plastic catheter is introduced, at the second anterior intercostal space in the mid-clavicular line, into the pleural space under local anesthesia using a sterile technique. The catheter is connected to a three-way stopcock and a large-volume syringe. Aspiration is performed until no further air can be withdrawn. Follow-up chest radiograph is performed. As there is a necessity for repeat aspiration or insertion of a catheter in a third of patients, placement of a small catheter attached to a

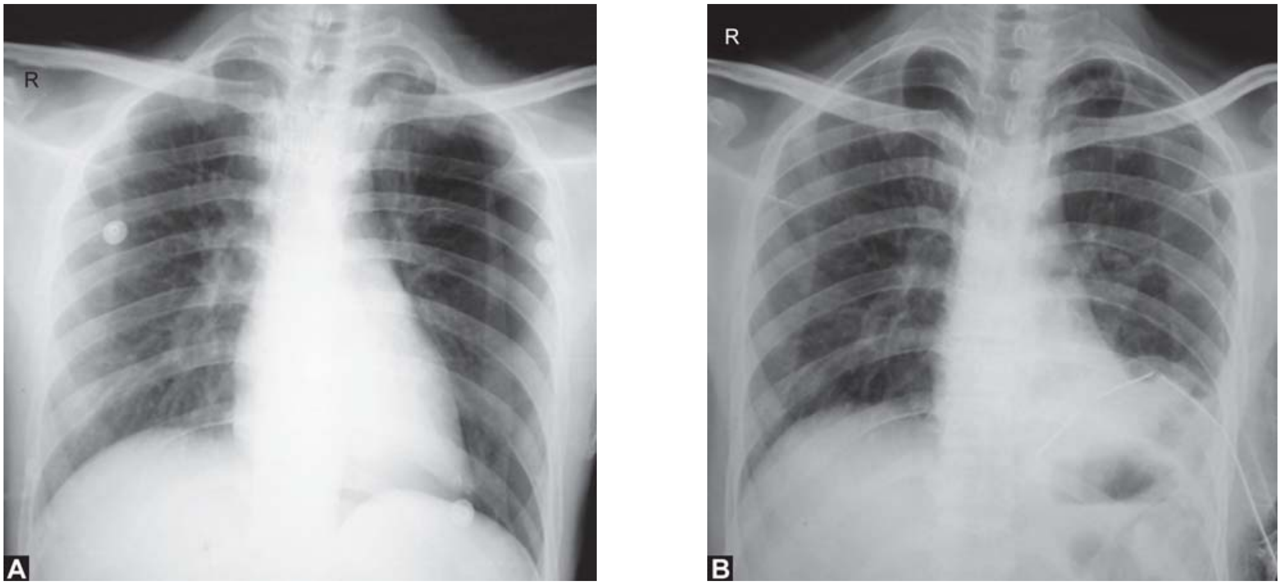
Heimlich valve followed by immediate discharge has been proposed as an alternative management.[21]

Tube Thoracostomy

Tube thoracostomy is recommended if simple aspiration is ineffective and thoracoscopy is not readily available; it rapidly results in the re-expansion of the underlying lung and does not require prolonged hospitalization.[29,30,31] A water seal is used with intercostal tube drainage which allows bubbling of air to be easily recognized. However, use of a flutter valve instead is advantageous in that it allows outpatient management, but care is required to ensure that it is connected correctly.

Smaller intercostal tubes (sizes from 14 to 22 French) minimize the discomfort, but larger size tubes (24–28 French) may be required, if the patient is unstable and has a large pneumothorax, if the patient is suspected to have a large bronchopleural fistula (air leak), hemopneumothorax or is at risk for positive-pressure ventilation (Figs 158.8 and 158.9).

Suction should be avoided for the first 24 hours of tube thoracostomy to reduce the risk of re-expansion pulmonary edema. Randomized studies have shown that



Figs 158.8A and B: Intercostal tube drainage for left sided pneumothorax

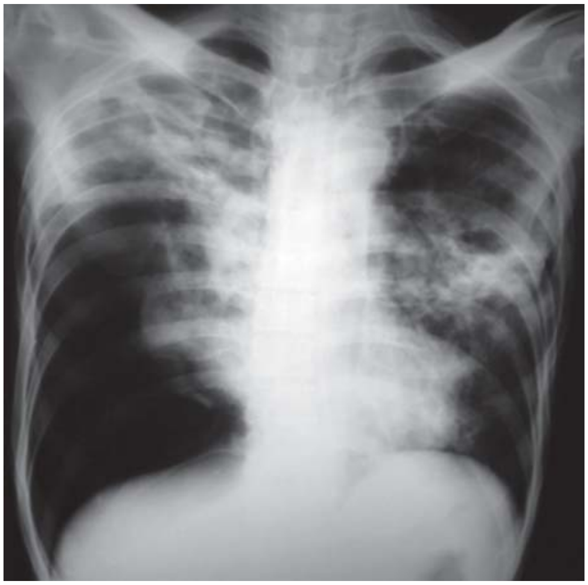


Fig. 158.9: Right spontaneous pneumothorax secondary to tuberculosis

applying suction to chest drains delays tube removal and lengthens hospital stay. Air leaks are present when there is persistent bubbling through the water seal chamber of the drainage system. If there is no bubbling on quiet respiration, the patient should be asked to cough. The absence of bubbling indicates that there is no air leak. Clamping of the intercostal drain is not advised as it confers no advantage if the air leak has stopped, but if it has not a dangerous situation may develop unrecognized. After the lung has re-expanded and the air leak has ceased for 24 hours, the chest tube can be removed.

Persistent Air Leak

In PSP, air leak would have already ceased in two third at the time of presentation and in 88% within the next week. Hence intervention with video assisted thoracoscopy or open thoracotomy, should be considered when the air leak persists beyond five days in PSP.

Pleurodesis

Pleurodesis is done with the help of tube thoracostomy and instillation of a sclerosing agent.

The goal of pleurodesis is to prevent recurrence in both PSP and SSP. Pleurodesis is a procedure that causes the symphysis of the two pleural membranes. Medical intervention consists of chemical pleurodesis using agents such as quinacrine, silver nitrate, talc or tetracycline derivatives. Chemical pleurodesis creates an intense inflammatory reaction which obliterates the pleural space. Talc slurry (100 mg/kg) results in effective pleurodesis but may be associated with Acute Respiratory Distress Syndrome (ARDS), hypoxia and hypotension in a small number of patients. ARDS is probably more common if smaller talc particles (<10 µm) are used.

Parenteral preparation of tetracycline (35 mg/kg) or doxycycline (10 mg/kg), or 20 ml 10% iodopovidone and 80 ml normal saline solution are effective in producing pleurodesis in patients.[32,33] Since severe chest pain is a common side effect with tetracycline pleurodesis, adequate analgesia is indicated prior to the procedure.

Recurrence rates can be reduced from approximately 40 to 25% by pleurodesis and to 5% by stapling of pleural bleb and pleural abrasion through a thoracoscopic procedure. Hence the latter is preferred when available, but in most centers it would not be available and chemical pleurodesis may be an acceptable alternative.

Thoracoscopy

Video-assisted Thoracoscopic Surgery (VATS) is being increasingly used in patients with PSP. The current indication is usually in recurrent PSP.[34,35] The entire lung can be inspected and a search for the cause of air leak carried out. VATS is appropriate for recurrent PSP or SSP. VATS with resection of large bullous lesions is associated with a recurrence rate of 2 to 14%. Pleural blebs responsible for pneumothorax are treated by a method called endo-stapling or suturing followed by pleurodesis by pleural abrasion.

In a meta-analysis of 12 trials that randomized 670 patients, VATS was associated with shorter length of stay (reduction 1.0–4.2 days) and less pain or use of pain medication than thoracotomy in 5 out of 7 trials. In the treatment of pneumothorax, VATS was associated with substantially fewer recurrences than pleural drainage in two trials. In one study of 59 patients, pleuroscopy with the insufflation of talc had a recurrence rate of 5% during a follow-up period of five years.[36]

More recent studies suggest that it may be the procedure of choice. It causes less postoperative discomfort than regular surgery. In addition the length of hospital stay is reduced even in patients with a first attack.[36] The recurrence rates and the days on CTD are also decreased.

Open Thoracotomy

Open thoracotomy with suturing of the blebs and pleural abrasion is a reasonable alternative when VATS is not available. A transaxillary minithoracotomy is preferred, to minimize the trauma and the length of the scar.

Indications for operative management are:

1. First recurrence
2. High-risk professions/lifestyles such as pilots or scuba divers
3. Bilateral or tension pneumothorax[21,23]

Persistent air leak after 72 hours, patients with previous forms of therapy resulting in incomplete re-expansion of the lung and patients from remote areas without ready access to medical care are relative indication for surgical care during the first occurrence, due to the risk to patient should the pneumothorax recur.

SECONDARY SPONTANEOUS PNEUMOTHORAX

Pneumothorax occurring in patients with underlying lung disease is more serious as previously diminished lung function is further compromised with the occurrence of pneumothorax and can be life threatening. Secondary Spontaneous Pneumothorax (SSP) may be associated with a host of underlying lung diseases, with pulmonary tuberculosis being the most common condition reported in India and Chronic Obstructive Pulmonary Disease (COPD) the most common condition in the western world. In Olmsted County, Minnesota, the incidence of SSP was 6.3/1,00,000/year for males and 2.0/1,00,000/year for females.[37] On an average, patients with SSP are 15–20 years older than patients with PSP. The incidence of SSP peak occur a little earlier in Indian population (40–50 years) as compared to the 60–65 years range reported in the Western studies.[6] The recurrence risk of 40 to 80% in SSP is higher than that for PSP.

Though the above table is fairly exhaustive, almost every other pulmonary disease has been associated with SSP. In a study of 60 patients in north India, the most common etiology for SSP was identified as pulmonary tuberculosis followed by COPD and pyogenic infections. Acquired Immunodeficiency Syndrome (AIDS) associated pulmonary infections were seen in four (8.3%) patients with SSP.[6]

Clinical Manifestations

As lung function in these patients is already compromised, SSP often presents as a potentially life-threatening condition, requiring immediate action. In SSP, dyspnea is the most prominent clinical feature; chest pain, cyanosis, hypoxemia and hypercapnia, sometimes resulting in acute respiratory failure, can also be present. Diagnosis is confirmed on a posteroanterior chest radiograph; in bullous emphysema, the differential diagnosis with a giant bulla can be difficult, necessitating CT confirmation. The apparent pleural line with a large bulla is usually concave toward the lateral chest wall because it represents the medial border of the bulla, whereas the pleural line with a pneumothorax is usually oriented convexly toward the lateral chest wall (Figs 158.10A and B).

TABLE 158.2: Etiology of secondary spontaneous pneumothorax

Infection	*Malignancy*
Tuberculosis (most common cause in India)	Primary lung carcinoma
P. jiroveci pneumonia	Pulmonary metastasis (especially sarcomas)

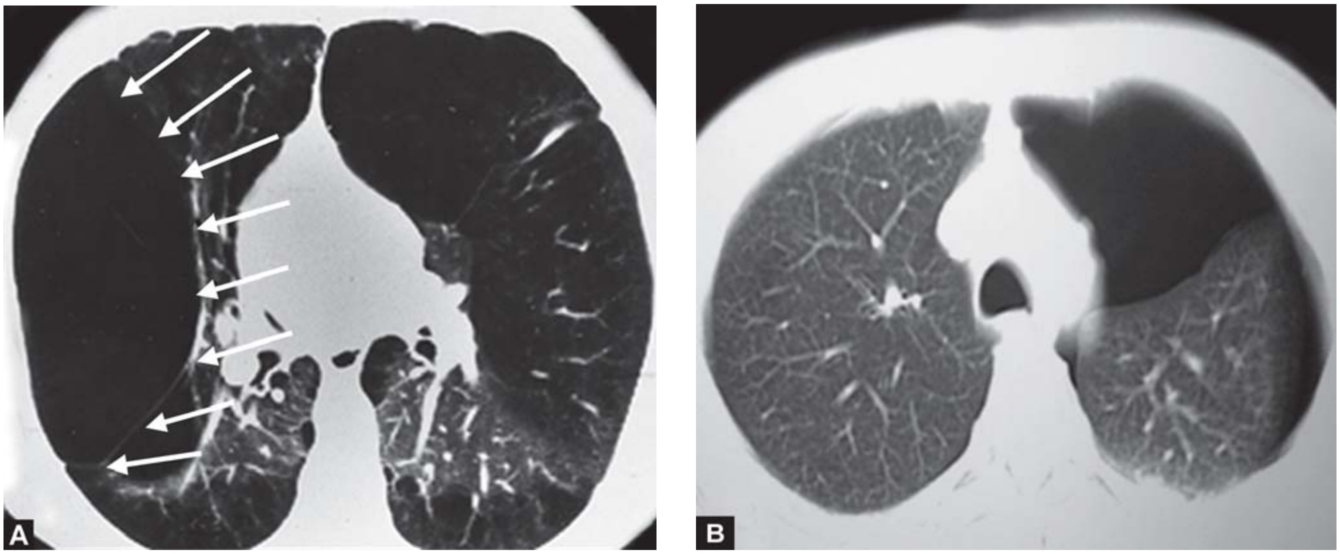
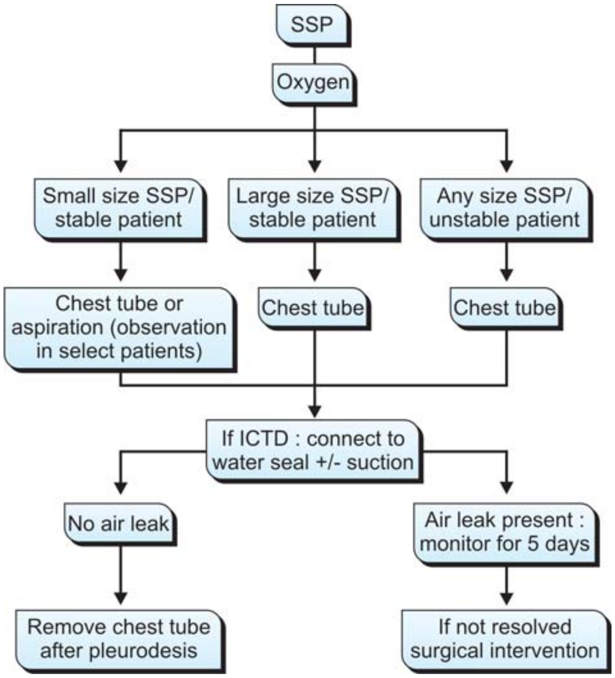
Histocytosis X	Pulmonary alveolar proteinosis
	Tuberous sclerosis
	Von Recklinghausen's disease
	Wegener's granulomatosis



Figs 158.10A and B: Comparison of bullous emphysema (A) and pneumothorax (B)

Management

SSP requires immediate air evacuation followed by prevention of recurrence at the first episode. All patients with SSP should be hospitalized. Awaiting recurrence prevention treatment, air evacuation can be achieved by simple manual aspiration in young (<50 years old) patients with small pneumothoraces, but most authors and guidelines recommend immediate insertion of a chest tube.[21] The evacuation of even a small pneumothorax can lead to a rapid improvement in symptoms. If respiratory failure occurs, necessitating mechanical ventilation, a chest tube should be placed immediately because the pneumothorax is likely to enlarge during mechanical ventilation (Fig. 158.11).



SSP
Oxygen
Small size SSP/ stable patient
Large size SSP/ stable patient
Any size SSP/ unstable patient
Chest tube or aspiration (observation in select patients)
Chest tube
Chest tube
If ICTD : connect to water seal +/- suction
No air leak
Air leak present : monitor for 5 days
Remove chest tube after pleurodesis
If not resolved surgical intervention

Fig. 158.11: Algorithm for management of secondary spontaneous pneumothorax[38]

Small bore chest tubes and even pigtail catheters are usually sufficient; large-bore chest tubes are recommended when large air leaks are suspected or when positive pressure ventilation is required. Persistent air leak is more common in SSP, particularly in the elderly. Recurrence prevention should preferably use a thoracoscopic approach; in case a visible air leak is present (e.g. a ruptured emphysematous bulla), it should be closed by electrocautery or stapling. In all cases, pleurodesis should be done using talc poudrage, pleural abrasion or partial pleurectomy. Patients in whom lung transplantation is a possibility in the future (e.g. cystic fibrosis, some cases of COPD), the transplant team should be consulted on whether to perform pleurodesis or not. Most transplant teams do not consider pleurodesis as a contraindication for transplantation.

Pneumothorax Secondary to Tuberculosis

In a study of 60 patients, tuberculosis (41%) was the most common etiology for SSP in India. SSP associated with tuberculosis should be treated with tube thoracostomy and often requires prolonged periods of chest tube drainage. Surgery should be delayed if possible till he or she has received antituberculous therapy for at least six weeks.

Pneumothorax Secondary to Pneumocystis in Patients with Acquired Immunodeficiency Syndrome

Pneumothorax in patients with AIDS is associated with multiple etiologies. Pneumocystis jiroveci, pyogenic infections, Kaposi's sarcoma, cytomegalovirus, pulmonary cryptococcus, coccidiomycosis and mycobacterial disease have all been associated with spontaneous pneumothoraces.[2] Most patients have a $CD4^+$ count less than 100 cells/mm^3. Approximately 5% of patients with AIDS who receive prophylactic pentamidine develop a spontaneous pneumothorax. This population also has higher risk of contralateral pneumothorax and iatrogenic pneumothorax because of frequent pulmonary procedures or need for ventilation. SSP associated with *P. jiroveci* is notoriously difficult to treat due to the necrotizing nature of the pneumonia. All patients with SSP, due to associated AIDS, should undergo tube thoracostomy. Heimlich valve or VATS is indicated if air leak persists for more than a few days.

Chronic Obstructive Pulmonary Disease (COPD) and Asthma

Pneumothorax is a well recognized, potentially lethal and often hard to treat complication of emphysema (39). COPD is the leading cause of SSP in the West, while it accounts for only 25% cases of SSP in India. Pneumothorax occurs in less than two percent of adults with acute asthma.

Cystic Fibrosis (CF)

Pneumothorax is a serious complication in patients with cystic fibrosis. Pneumothorax in CF patients is associated with a high rate of mortality and is an indicator of a poor prognosis. The risk of developing a pneumothorax increases as age increases and pulmonary function (FEV_1) decreases. The presence of *P. aeruginosa, Burkholderia cepacia*, and *Aspergillus* in the airways increases the risk of pneumothorax by causing increased inflammation, airway secretions and air trapping. Recurrence rates are high and hence preventive measures have to be taken with the first episode of pneumothorax.[40]

Catamenial Pneumothorax

Pneumothorax that occurs in conjunction with menstruation is called catamenial pneumothorax. Respiratory symptoms usually develop within 24–48 hours of the onset of the menstrual flow.[41] Catamenial pneumothoraces are more common on the right side. This is due to transperitoneal migration of endometrial tissue from the pelvis through small defects in the right diaphragm. Left-sided and even bilateral pneumothoraces have also been reported. Catamenial pneumothoraces tend to be recurrent unless there is a therapeutic intervention.

The treatment of catamenial pneumothorax is aimed at treating endometriosis, by suppressing the ectopic endometrium. This can be attempted by suppression of ovulation with oral contraceptives or by suppression of gonadotropins with danazol or gonadotropin-releasing hormone to produce a medical oophorectomy. Alternative treatments include thoracoscopy with stapling of blebs, closure of diaphragmatic defects and parietal abrasion or pleurectomy, or chemical pleurodesis.

Iatrogenic Pneumothorax

Iatrogenic pneumothoraces are more common than primary and secondary spontaneous pneumothoraces combined. The leading cause of iatrogenic pneumothorax is transthoracic needle aspiration. Pneumothorax is more likely if the patient has underlying COPD, if the lesion is deep within the lung, or if the angle of the needle route is wide. Other causes are transbronchial biopsy, thoracentesis, pleural biopsy, central vein catheterization, ventilation with high levels of positive end-expiratory pressure, tracheostomy, intercostal nerve block, mediastinoscopy, liver biopsy and cardiopulmonary resuscitation.[23]

Diagnosis of iatrogenic pneumothorax is often delayed, which should make physicians vigilant. Small and asymptomatic iatrogenic pneumothoraces often do not need any treatment, and resolve spontaneously. In larger or symptomatic pneumothoraces, simple manual aspiration or placement of a small catheter or chest tube attached to a Heimlich valve is usually successful. Larger tubes may be necessary in emphysematous patients or when mechanical ventilation is indicated.

Traumatic (Non Iatrogenic) Pneumothorax

A traumatic pneumothorax can result from either penetrating or nonpenetrating chest trauma. In penetrating injuries, the object penetrating the chest disrupts the visceral pleural surface prompting air to enter from the lung or allows air entry through the breached chest wall. With blunt chest trauma, pneumothorax is either due to a rib fracture lacerating the visceral pleura or due to abrupt elevation in the alveolar pressure causing alveolar rupture. Air may then dissect toward either the visceral pleura or the mediastinum. A pneumothorax develops when either the visceral or the mediastinal pleura ruptures.

Traumatic pneumothoraces may be occult, not seen on chest radiograph but found by additional imaging. A substantial number (29 to 72%) are occult, emphasizing the need for a high index of suspicion and early routine computed tomography in all chest and multitrauma patients.[42] Thoracic ultrasonography, which can be done at the bedside as part of an extended focused assessment for trauma patients can detect most (92 to 100%) pneumothoraces.

Most traumatic pneumothoraces should be treated initially with tube thoracostomy. If the patient has an occult pneumothorax or if the distance between the lung and chest wall is less than 1.5 cm, tube thoracostomy is probably not indicated unless the patient is receiving mechanical ventilation. Fracture of the trachea or a major bronchus, and traumatic rupture of the esophagus are uncommon causes of traumatic pneumothorax and an immediate thoracotomy is indicated. Rupture of the esophagus is accompanied by hydropneumothorax and the pleural fluid amylase concentration is raised. Mortality approaches 100%, if surgical treatment is not carried out promptly.

Tension Pneumothorax

Tension pneumothorax is present when the intrapleural pressure exceeds atmospheric pressure throughout expiration and frequently during inspiration. Most patients suffering a tension pneumothorax are receiving positive pressure to their airways, either during mechanical ventilation or during resuscitation.[23] Tension may also develop in spontaneously breathing patients, in the presence of a one-way valve process permitting air to enter the pleural space during inspiration but not exit during expiration.

Presentation is abrupt with sudden deterioration in the cardiopulmonary status of the patient. Decreased cardiac output due to impaired venous return and profound hypoxia due to ventilation-perfusion mismatch results in severe cardiopulmonary compromise. Patients with tension pneumothorax present with severe distress, displaying cyanosis, diaphoresis, tachycardia, hypotension and labored breathing. Treatment should not be delayed pending radiographic conformation, especially in a mechanically ventilated patient. When the diagnosis is suspected, the patient should immediately be given a high concentration of supplemental oxygen to alleviate the hypoxia. A large-bore (14- to 16-gauge) catheter with needle should be immediately inserted into the pleural space through the second anterior intercostal space. This confirms the diagnosis by usually eliciting an audible rush of air from the pressurized pleural space. Alternatively, the needle may be fitted with a partially sterile-water filled syringe and introduced into the pleural space until air is aspirated. Marked bubbling after the syringe plunger is removed confirms the diagnosis. Placement of the needle through the lateral fifth intercostal space may be safer, though the second anterior space had been previously advocated. Immediately thereafter, intercostal tube drainage should be placed.

Summary

Primary spontaneous pneumothorax is an important cause of sudden occurrence of chest pain and acute breathlessness in young adults. Secondary spontaneous pneumothorax outnumbers PSP in the general population. Prompt treatment relieves patient of his symptoms and can be life saving. Simple aspiration is the preferred initial method of drainage. Recurrence rates after first episode of PSP is 30 and 40 to 80% in SSP. Effective recurrence prevention can be done by chemical pleurodesis in resource constrained settings. Thoracoscopic intervention is preferred when available.

Malignant Pleural Effusions

Srinivas Rajagopala, George D'Souza

INTRODUCTION

Malignant pleural effusions (MPE) constitute the second most common cause of exudative pleural effusions in the developing countries. On the other hand, malignancy is the most common cause in the developed countries, where the incidence of tuberculosis is low.[1-3]

ETIOLOGY OF MALIGNANT EFFUSIONS

About 50 to 65% of MPE are associated with lung and breast cancer,[1] while 25% are associated with lymphoma, gastrointestinal and genitourinary cancers. Sarcomas (including melanomas), germ cell tumors and prostatic carcinoma together account for about 10% of all MPE[4] while the primary source of malignancy is unknown in the remaining 7 to 15% of patients. The diagnosis of pleural malignancy is the first indication of cancer in about 10% of effusions.[5] Primary pleural malignancy is an uncommon cause of malignant pleural effusion and metastatic malignant pleural effusions are 25-fold common than mesotheliomas even in areas where the latter are relatively common.[6] Pleural effusion in a patient with lung cancer is a poor prognostic marker and the recent TNM classification has upstaged these patients to stage 4A.[7]

In India, no systematic data exists on the proportion of different etiologies of exudative pleural effusions in routine clinical practice. A retrospective review of 236 exudative pleural effusions from our institution over a one-year period (2005-2006) showed that tuberculosis (66.9%, N=158) was followed by malignancy (13.1%, N=31) as the most common causes of exudative pleural effusions (unpublished data). A second retrospective analysis over a five months period (January-May 2010) of 64 exudative effusions (20% of total admissions over that period) showed that malignancy (36%) was the most common cause of exudative pleural effusion; tuberculosis (34%), parapneumonic effusions/empyemas (17%) and pulmonary thromboembolism (6.25%) were the other common causes (unpublished data). With the virtual epidemic of lung cancer in India,[8,9] clinicians will increasingly face the challenge of diagnosing and managing patients with malignant pleural effusions.[10] Bidi smoking and biomass fuel use continue to fuel this epidemic in India.[11] Most patients with lung cancer present with advanced disease in India and the one-year survival has been reported as 9.8%.[12] Approximately half of all patients with metastatic lung cancer develop a malignant pleural effusion and have a significant reduction in quality of life because of the effusion.

Pleural effusions are present in 15% of patients of lung cancer at diagnosis, 50% of patients develop effusion during their disease course.[13] Adenocarcinomas are most frequently associated with malignant pleural effusions, although effusions may be seen with all the histopathological types of cancer.[14] Anti-p53 positivity increases the risk of pleural effusion in patients with carcinoma lung.[15] Breast cancer is the second most common cause, the time from the initial diagnosis to development of effusion is usually two years, but can extend up to 20 years. About 43% of patients with disseminated disease develop pleural effusions. The effusion is usually ipsilateral (70%) but can be contralateral (20%) or bilateral (10%).[16] Pleural effusions are also common in both Non-hodgkin Lymphoma (NHL) and Hodgkin Lymphoma (HL). About 40% of NHL and 16% of patients with HL have an associated effusion. Effusions in HL are associated with mediastinal lymphadenopathy and in NHL with evidence of disease elsewhere. About 3% of effusions related to HL and 20% of effusions related to NHL are chylothoraces.[17]

PATHOGENESIS OF METASTASIS AND EFFUSIONS

Pleural metastases occur by several mechanisms like pulmonary vascular invasion with tumor emboli to the visceral pleural surface with subsequent seeding of the parietal pleura, direct tumor invasion, hematogenous metastases to the parietal pleura from extrapulmonary primaries, and lymphatic involvement.[18] In lung cancer, pulmonary artery emboli and ipsilateral visceral pleura invasion (invasion beyond the elastic layer including invasion to the visceral pleural surface) is the first step.[19] Tumor seeding of the parietal pleura always follows visceral pleural involvement.[20] Pleural metastases may be present without associated effusion.[18,20] In one autopsy series of disseminated malignancy, pleural metastases were seen in 29% and pleural effusions were present in less than half of these patients.[18] Pleural lavage during thoracostomy for lung cancer surgery correlates with visceral pleural involvement and a positive lavage is associated with shortened survival.[21]

Malignant pleural effusions (malignant cells identified in pleural fluid or pleural tissue with associated effusion) are formed by several mechanisms, which may be direct or indirect (Table 159.1). Increased pleural permeability secondary to production of Vascular Endothelial Growth Factor (VEGF) is largely responsible for the development of MPE.[22,23] Lymphatic blockade in the parietal pleura stoma and at the lymph nodes also contributes to generation of MPE; pleural involvement and intrathoracic lymphadenopathy correlate with pleural effusions related to malignancy in autopsy studies.[18,20] In general, direct involvement of pleura by the malignancy makes it inoperable and the treatment approaches are predominantly palliative. However, "paramalignant" causes of effusion, especially pneumonia, pulmonary embolism and atelectasis may be operative in about 17% of cases and this should be ruled out before palliation alone is considered.[24]

CLINICAL PRESENTATION

Malignant pleural effusions may occur in a patient with diagnosed malignancy or may be the first sign of disseminated malignancy. In the first instance, clinical evaluation proceeds to confirm that the pleural cytology is positive and the symptoms guide the patient management; in the latter instance, clinical evaluation proceeds to evaluate the etiology of the effusion. Once the pleural cytology or histology is positive, a search for the primary malignancy has to be made to guide further management.

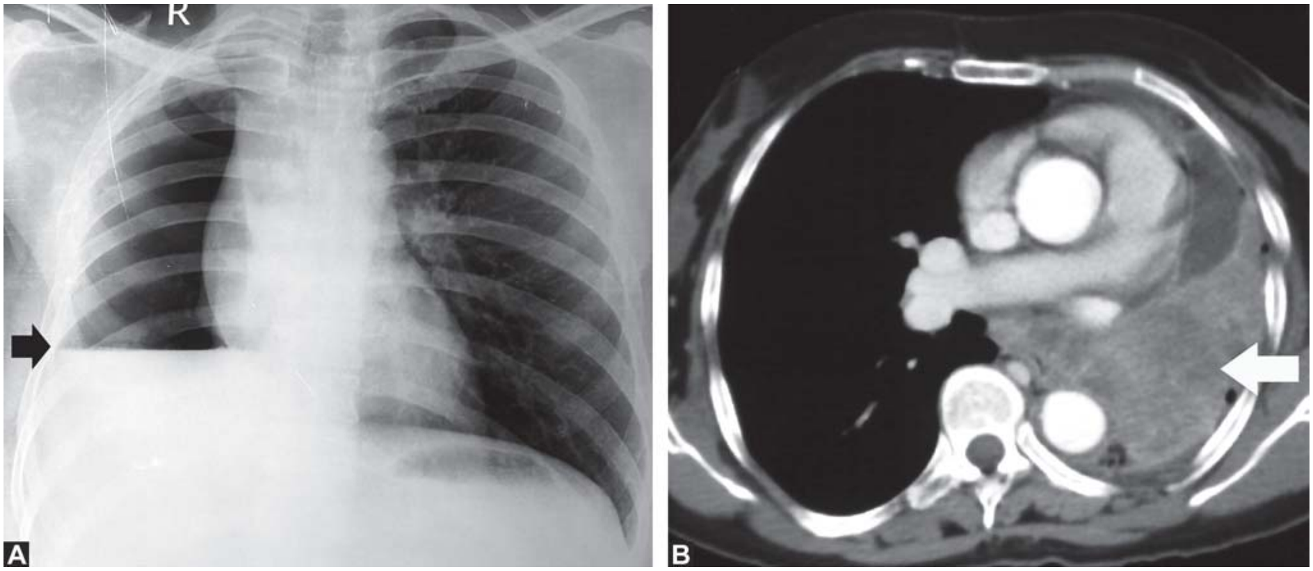
In either case, breathlessness is the most common presenting symptom in patients with MPE, occurring in more than half of the patients. The pathogenesis of dyspnea from a large pleural effusion appears to be related to decreased chest wall compliance, contralateral mediastinal shift, decreased ipsilateral lung volume and reflex stimulation from the chest wall and lung parenchyma. Nonproductive cough may also be caused by the presence of a pleural effusion. Both dyspnea and cough are relieved promptly by thoracentesis; failure of improvement suggests tumor infiltration of lung or pleura or another associated medical condition as the etiology of the pleural effusion.

Patients may also complain of systemic symptoms such as malaise, anorexia and weight loss which is related to the advanced stage of malignancy. A constant dull, aching chest pain may be present; however, this is more common in patients with mesothelioma.[24] Chest pain is related to malignant involvement of the parietal pleura, ribs and other intercostal structures. Patients with benign causes of their effusions are more likely to describe "pleuritic" chest pain. The presence of hemoptysis suggests an endobronchial growth as the primary etiology. A history of smoking and occupational exposure to asbestos may suggest the diagnosis of MPE. Symptoms of more than a month, absence of fever and serosanguineous fluid on thoracocentesis also favor the possibility of malignancy.[25]

When an effusion is the only sign of malignancy and the primary is unknown, the evaluation should include computed tomography of thorax, abdomen and pelvis and mammography in women.[26] Bronchoscopy is always negative when the chest-Computed Tomography (CT) does not demonstrate an abnormality.[26] Any abnormality in this evaluation (34% of 42 patients, all had lung primary) is confirmed by further invasive testing. If these are negative, no additional tests are required and the patient is managed as per Carcinoma of Unknown Primary Syndrome (CUPS) protocol.

RADIOLOGICAL FINDINGS

At presentation, patients with MPE typically have an effusion occupying half to two third of the hemithorax. While small effusions are seen in about 10%, an additional 10% present with a massive pleural effusion. Massive effusions are malignant in etiology in 55 to 70% of cases.[27]



Figs 159.1A and B: Composite image of chest radiograph (A) showing right-sided hydropneumothorax following thoracocentesis and lung entrapment due to a thick visceral pleural peel. The computed tomography image (B) shows a large intra-bronchial mass, loculated effusion and ipsilateral mediastinum

A massive effusion is associated with contralateral shift of the mediastinum. When there is an absence of contralateral mediastinal shift with an apparent large pleural effusion, bronchogenic carcinoma involving the ipsilateral mainstem bronchus (Fig. 159.1A), malignant mesothelioma, fixation of the mediastinum due to malignant lymph nodes or lung entrapment by extensive pleural malignancy should be suspected (Fig. 159.1B). Multiloculation at presentation is unusual in malignant effusions (unlike parapneumonic effusions) because of the high fibrinolytic activity of the metastatic tumor lesions.[28] Chest radiographs of patients with lung primary and an effusion often demonstrate the presence of associated abnormalities; these might sometimes be apparent after a therapeutic thoracocentesis.

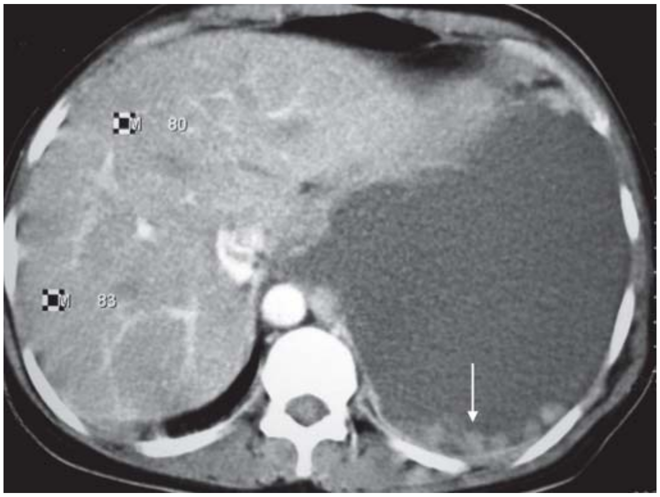


Fig. 159.2: Computed tomography showing left-sided effusion and multiple pleural nodules. Pleural biopsy showed adenocarcinoma

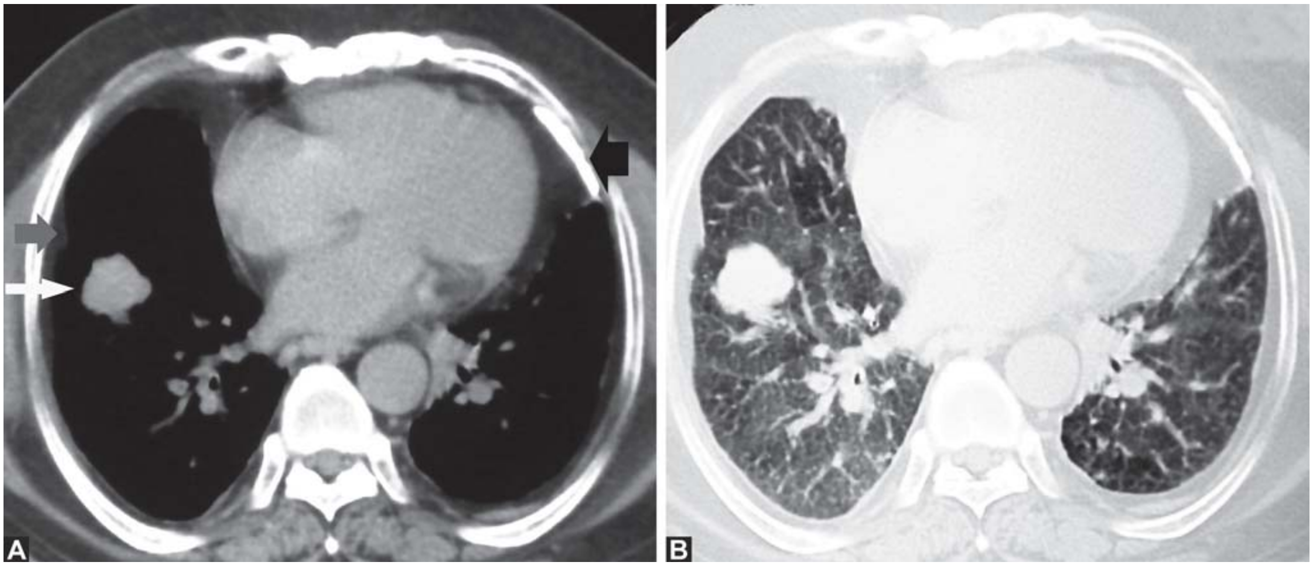
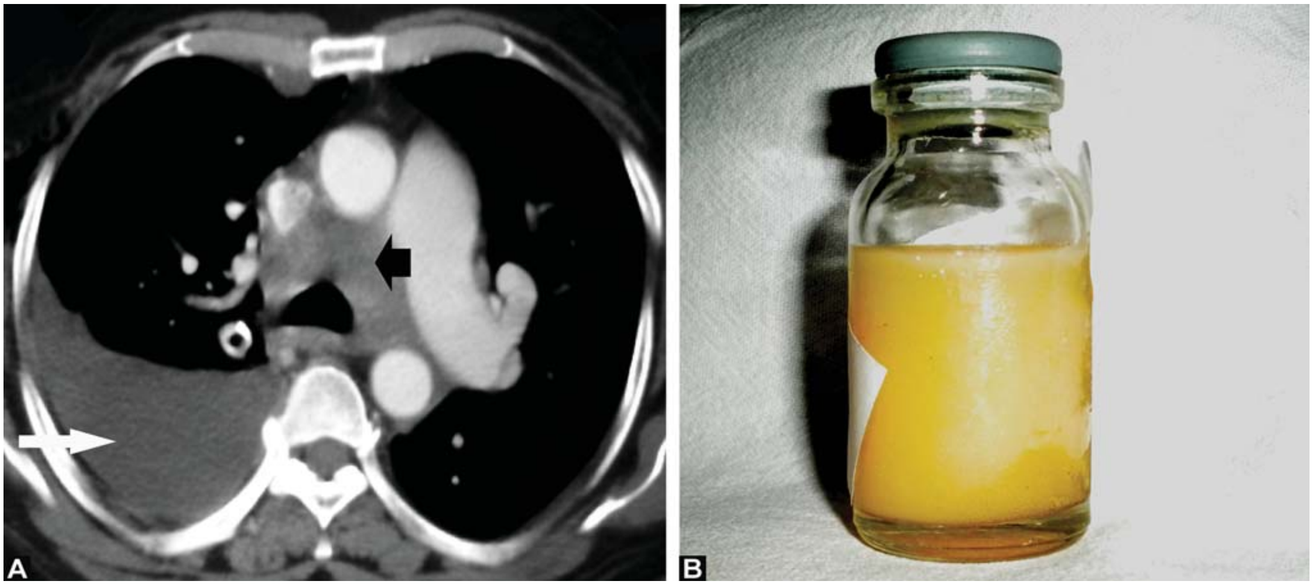
Computerized tomography of the chest should include upper abdomen to enable visualization of possible adrenal and hepatic metastasis. The diagnosis of malignant pleural thickening is favored by the presence of parietal pleural thickening of greater than 1 cm, circumferential pleural thickening, nodular pleural thickening and mediastinal pleural thickening (specificity 94 to 100%).[29] CT of the chest may be helpful in the evaluation of patients with malignant effusion by demonstrating pleural abnormalities (Figs 159.2 and 159.3A and B), mediastinal lymphadenopathy (Figs 159.4A and B), parenchymal disease, distant metastases, chest wall and airway involvement that cannot be detected on standard chest radiograph. CT appearances of mesothelioma may be very similar to metastatic pleural effusion. Presence of concomitant pleural plaques (20%), asbestosis, extensive chest wall invasion, circumferential nodular lung encasement, pleural thickening with irregular pleura-pulmonary margins, inter-fissure thickening and pleural thickening with superimposed nodules should suggest mesothelioma.[30,31] Magnetic resonance imaging is



Figs 159.3A and B: Composite image of computed tomography showing pleural calcification (left, black arrow) and a nodule (black arrow) in the right lower lobe with a minimal right-sided effusion. Fine needle aspiration and immunohistochemistry from the nodule confirmed adenocarcinoma



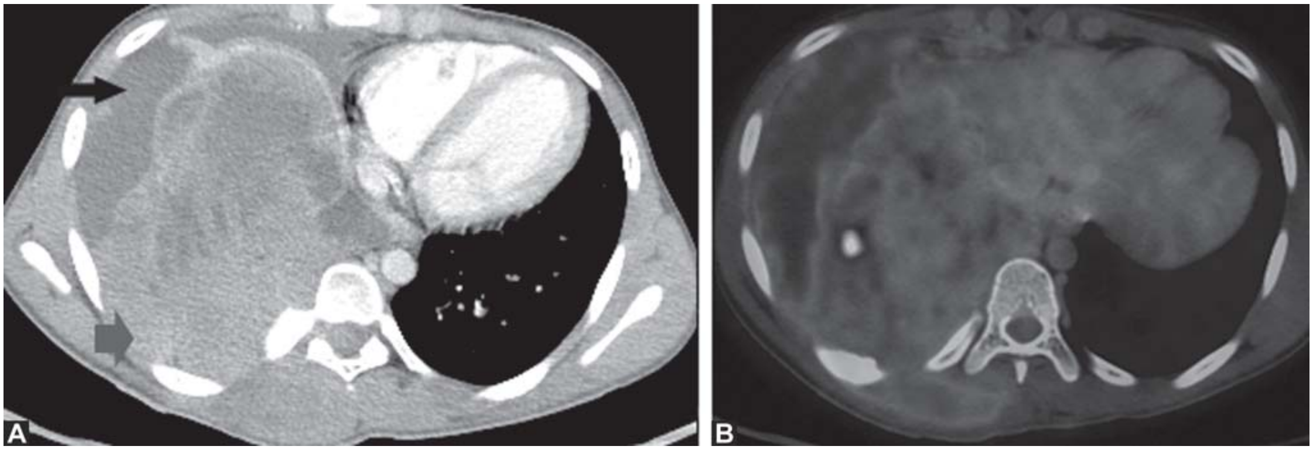
Figs 159.4A and B: Composite image of computed tomography (left) showing right moderate pleural effusion (black arrow) and mediastinal lymphadenopathy (white arrow). Thoracocentesis suggested a chylothorax (triglyceride 150 mg/dl and cholesterol of 45 mg/dl, right) and mediastinoscopic biopsy confirmed lymphoma.

not commonly performed in patients with MPE; it may be helpful in evaluating chest wall involvement. Positron emission tomography may be helpful in evaluating the extent of pleural involvement in malignant mesothelioma but does not offer additional information of routine use in patients with MPE (Figs 159.5A and B).

DIAGNOSIS

Pleural Fluid Analysis

Malignant pleural effusions can be serous, hemorrhagic or grossly bloody while malignant disease is the most



Figs 159.5A and B: Composite image of computed tomography (left) showing right moderate pleural effusion (black arrow) and a large right lower lobe mass (red arrow). CT-guided biopsy established the diagnosis of Askin's tumor. Positron Emission tomography images (right) shows an area of increased uptake in the right lower lobe corresponding to the mass.

TABLE 159.1: Mechanisms for formation of pleural effusions in relation to malignancy

1. *Direct*
   - Increased capillary permeability from direct pleural invasion
   - Lymphatic obstruction due to malignant lymphadenopathy
   - Disruption of thoracic duct or its major tributaries (chylothorax)[@]
2. *Indirect (Paramalignant)*[$]
   - Bronchial obstruction with atelectasis
   - Bronchial obstruction with pneumonia
   - Lung entrapment by malignancy (thick visceral pleural involvement)
   - Hypoalbuminemia (serum albumin <1.5 g/dl)
   - Pulmonary embolism
   - Malignant pericardial involvement
   - Superior vena cava syndrome
   - Radiation therapy
     - Early (<6 months): Pleuritis 6 weeks to 6 months after radiation
     - Late (>6 months)
       - Mediastinal fibrosis
       - Constrictive pericarditis
       - Superior vena cava obstruction
   - Chemotherapy (Methotrexate, cyclophosphamide, mitomycin, procarbazine, bleomycin)

[@] Most commonly seen with lymphomas
[$] Do not indicate nonoperability when seen with carcinoma lung

common cause of hemorrhagic effusion. About 50% of MPE are nonhemorrhagic and have red blood cell counts of <10,000 cells/ µl. The pleural fluid is almost always an exudate but these effusions may occasionally fulfill light's criteria by an elevated Lactate Dehydrogenase (LDH) only. It is suggested that this finding is due to increased cell turnover being the source of the elevated LDH, without increased vascular permeability needed to produce pleural fluid with increased protein concentration. If the analysis suggests a transudate (<5%), then "paramalignant" causes must be considered (Table 159.1). Nucleated cell count is typically low, generally <3,000/µl, composed mainly of lymphocytes, macrophages and mesothelial cells. The lymphocyte differential count mostly varies from 50 to 70% of all cells. The presence of pleural eosinophilia does not negate the possibility of pleural malignancy and the prevalence of malignancy is similar in both eosinophilic and noneosinophilic effusions.[32]

The pleural glucose concentration is lower than 60 mg/dl in approximately 20% of MPE. Impaired glucose transfer to pleural fluid and glucose utilization by tumor burden contributes to the observed low-glucose levels.[33] Lactic acid generated by anaerobic glycolysis in the pleural space and impaired carbon dioxide movement from the pleural space are responsible for low pH generation. A low pleural fluid pH (<7.30) and a low pleural fluid glucose (<60 mg/dl) are markers of advanced disease in the pleural space with increased tumor burden;[34] this is also associated with a decreased survival,[35] a higher sensitivity of diagnosis by initial cytologic examination and less successful pleurodesis. Using a dichotomous level of 7.15 yields an Odds Ratio (OR) of 4.46 (95% CI 2.69-7.45) for failure of pleurodesis.[36] Using multi-level LR's provide better information than using a dichotomous L.R of <7.2 or ≥7.2.[37] However, pleural fluid pH is not an accurate predictor of pleurodesis failure (positive predictive value of 45.7% only for pH <7.2) or survival (LR 1.7, 95% CI 1.20–2.41 at three months) and should not be used in isolation for predicting these outcomes.[36-38] Successful pleurodesis in 88% despite pH of <7.3 and in 40% with a pH below 7 with thoracoscopic talc pleurodesis has been reported.[39] Increased amylase concentration is seen in 10–14% of patients with MPE, especially adenocarcinoma lung and ovary, usually due to increased salivary isoenzyme concentration.[40] The routine assay of amylase is unhelpful in the diagnosis of exudates of undetermined etiology and should be measured only if there is a pre-test suspicion of acute pancreatitis, chronic pancreatic disease or esophageal rupture.[41]

Pleural Cytology

The diagnosis of MPE is established by demonstrating malignant cells in the pleural fluid or in the pleura tissue. Pleural fluid cytology is diagnostic in up to 60% of patients with MPE depending on the tumor load and the histopathological type of the primary malignancy. Pleural cytology is rarely positive in squamous cell carcinoma because bronchial obstruction and lymphatic involvement are frequent causes of pleural effusion in this setting. A sample submitted for cytology need not exceed 50 ml in quantity.[42] Cell-block and cytology smear analysis increases the yield of positive tests and enable immunohistochemistry. A positive cytology establishes malignancy, but provides no information about the site of primary. This is evaluated by subsequent imaging, endoscopy or markers by immunohistochemistry (PSA, CA-125).

Pleural Biopsy

The sensitivity of percutaneous blind pleural biopsy using Abrams' biopsy needle varies between 40–75%, depending upon the extent of parietal pleural involvement, number and adequacy of biopsies and operator experience. If blind biopsy is performed before cytology, one third of patients, who could otherwise be diagnosed, will be missed. The low yield of percutaneous biopsy is because of the initial lesions which tend to establish on the visceral pleura followed by metastases along the mediastinal and diaphragmatic pleura. Further, the involvement may be patchy and missed on blind biopsy. Percutaneous blind biopsy is still used when the cytology is negative and thoracoscopy is unavailable. Computed tomographic-guided cutting needle biopsy is superior to blind Abrams needle biopsy with a yield of 87% versus 47% (N=50, P=0.02, 74% had mesothelioma).[43] Computed tomography-guided percutaneous pleural biopsy has a yield similar to thoracoscopic biopsy and may be performed when confirmation of the diagnosis (without the need for pleurodesis) is the dominant clinical problem.

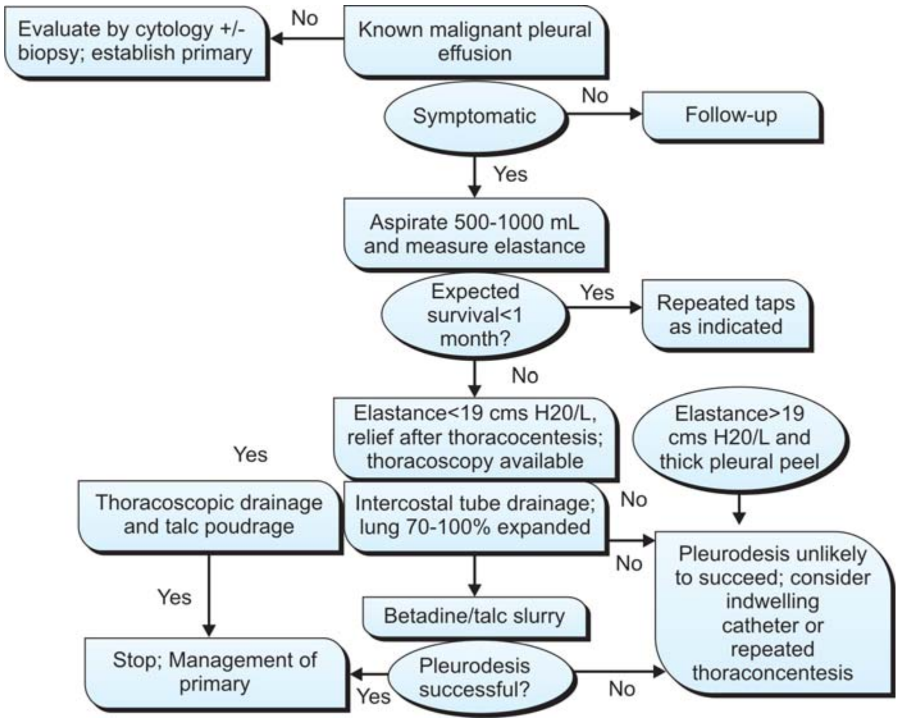
Medical thoracoscopy has a yield exceeding 95% for malignancy; further, this can be combined with complete drainage of the effusions, adhesiolysis and talc poudrage which has a greater percentage of successful pleurodesis (see below). Medical thoracoscopy can be performed using local anesthesia with conscious sedation in an endoscopy suite using nondisposable rigid instruments, making it less invasive and cheaper than video-assisted thoracoscopic surgery. The diagnostic yield and accuracy of thoracoscopy for malignant effusion exceeds 90%.[44,45] It is also safe and associated with low peri-procedure mortality (<0.5%).[46]

Tumor markers like Carcinoembryonic Antigen (CEA), Carbohydrate Antigens (CA) 15-3, 19-9, 549 and 72-4, neuron-specific enolase, SCC antigen, Cytokeratin 19 Fragments (CYFRA21-1) and Sialyl State-specific Mouse Embryonic Antigen (SSEA-1) have been evaluated to separate benign and malignant effusions. In general, these markers are not specific and have no role in daily practice.[47] In lymphoma, the clonality of lymphocytes demonstrated by flow cytometry on fluid samples establishes the diagnosis.

Immunohistochemistry is routinely used to differentiate adenocarcinoma from mesothelioma. Metastatic adenocarcinomas stain positive with CEA, MOC-3.1, B72.3, Ber-EP4 and BG-8, whereas mesotheliomas (and benign mesothelial cells) stain positive with calretinin and cytokeratin. A panel of four markers is usually employed in clinical practice.[14] Staining for Thyroid Transcription Factor-1 (TTF-1) in fluid and tissue can help establish pulmonary origin of adenocarcinomas.[48]

MANAGEMENT

The initial step is to establish malignancy and the site of the primary (Fig. 159.6). This guides subsequent chemotherapy and/or hormonal therapy and radiotherapy. The major indication for palliative treatment in patients with a malignant pleural effusion is the relief of dyspnea. The main considerations affecting management decisions include the patient's degree of breathlessness, functional status, duration of expected survival, type of primary tumor (expected response to



Evaluate by cytology +/- biopsy; establish primary

chemotherapy) and lung expansion following thoracocentesis. The following modalities are used in isolation or combined as the clinical situation dictates (Fig. 159.6).

Observation

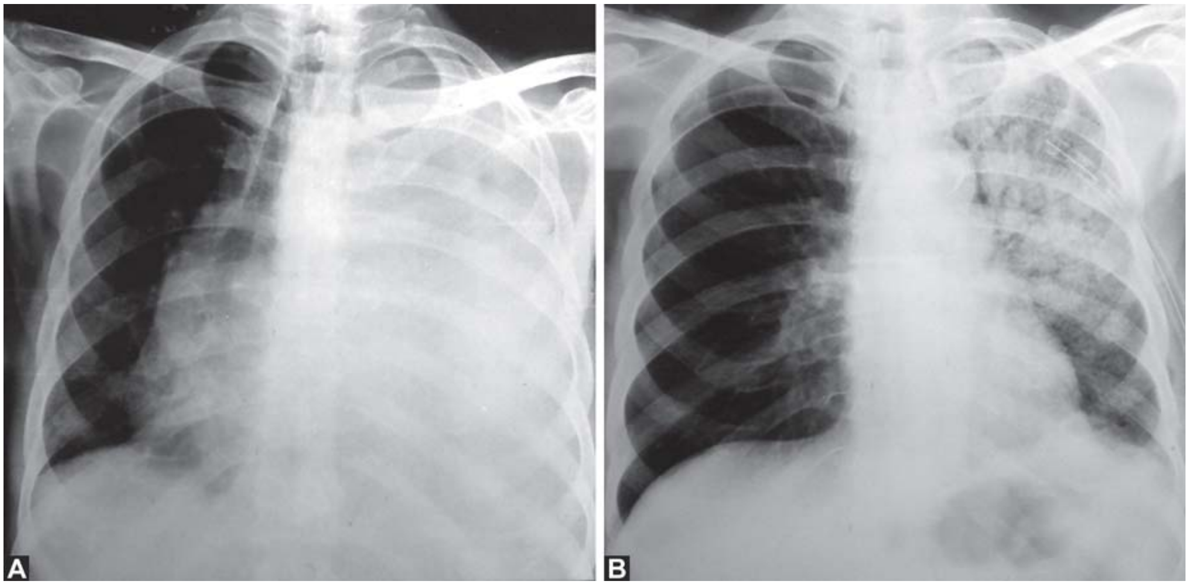
Observation is appropriate when patients are asymptomatic and neither therapeutic thoracocentesis nor pleurodesis are indicated in patients with asymptomatic mild-moderate effusions.

Chemotherapy and Radiation

Malignant pleural effusions from small-cell lung cancer, breast carcinoma and lymphoma may respond favorably to chemotherapy alone. If the effusion is mild-to-moderate, a trial of chemotherapy may be performed as a modality to control the effusion. In chylothorax from lymphoma, mediastinal radiation is effective. However chemotherapy is not useful in isolation to control the effusion, in most patients with MPE secondary to carcinoma lung. Anti-VEGF antibody bevacizumab has recently been approved for first-line treatment of non-small cell lung cancer. Pleurodesis should precede this treatment since VEGF is essential for successful pleurodesis.[49] In patients undergoing systemic chemotherapy, pleural effusions should be aspirated before chemotherapy is given because the antineoplastic drugs may accumulate in the pleural space and lead to increased systemic toxicity. Pleurodesis always precedes chemotherapy because the intercostal drain may become a potential nidus of infection.

Therapeutic Thoracentesis

Therapeutic thoracentesis is performed in all dyspneic patients with MPE for relief of breathlessness. Lack of improvement of dyspnea after thoracentesis implies an alternative associated condition like lymphangitic carcinomatosis, atelectasis, tumor embolism or thromboembolism. In our unit, the initial therapeutic thoracocentesis is always combined with pleural manometry and pleural elastance measurement (see the section on physiology of pleural diseases). Caution should be exercised when draining >1.5 L in a single session because of the potential of Reperfusion Pulmonary Edema (REPO) (Figs 159.7A and B). Using pleural manometry and limiting the procedure when pressure falls to -20 cms H_2O can guide safe thoracentesis in this setting. The amount of fluid evacuated by pleural aspiration should also be



Figs 159.7A and B: Composite image of chest radiographs of a patient with massive left-sided pleural effusion (left). Subsequent to thoracoscopy and intercostal tube drainage, the patient developed re-expansion pulmonary edema (right). The patient was managed with diuretics and oxygen and recovered at 48 hours.

guided by the presence of cough or chest discomfort. Mechanisms proposed for REPO include reperfusion injury of the underlying hypoxic lung, increased capillary permeability and local production of neutrophil chemotactic factors such as interleukin-8.[50] Caution must be exercised especially when the underlying lung has been collapsed for more than a week and large (>1.5 L) volumes are being drained as reperfusion edema complicates 2 to 7% of large volume thoracocentesis.[50] Re-expansion edema can also complicate thoracoscopic drainage of effusions.[51]

Therapeutic thoracocentesis alone has a high rate of symptom recurrence at one month, therefore, alternate options must be explored in all symptomatic patients. Therapeutic thoracentesis is used as the sole therapeutic option in advanced disease, poor performance status, tumors associated with a poor survival and pleural manometry studies suggesting lung entrapment. Repeated thoracocentesis in a patient who should undergo pleurodesis should be discouraged as this lead to formation of adhesions and hinders complete pleural evacuation (and subsequent pleurodesis).

Pleurodesis

Pleurodesis is a treatment that aims to produce symphysis of the pleural surfaces by chemical or mechanical means for symptom relief. The aim of pleurodesis in patients with malignant pleural effusions is to prevent re-accumulation of the effusion and the symptoms. Pleurodesis occurs through diffuse inflammation and local activation of coagulation with fibrin deposition. High intrapleural fibrinolytic activity,[52] high tumor burden and concomitant use of steroids[53] and possibly Non-Steroidal Anti-Inflammatry Drugs (NSAIDs),[54] reduce the effectiveness of pleurodesis. The initial event is injury to the pleural surfaces, followed by subsequent development of fibrosis with the obliteration of the pleural space. However, the mechanism of pleurodesis is highly complex, involves the intrapleural procoagulant-fibrinolytic milieu and angiogenesis pathways and differs from agent to agent.

Patient Selection, Initial Preparation and Procedure

Large pleural effusions are first drained incrementally with a maximum of 1.5 L on the first occasion. The intercostal tube is then clamped and any remaining fluid is drained 1.5 L at a time at two-hourly intervals. The procedure is stopped when cough, chest discomfort or vasovagal symptoms occur and re-started after an interval of 12–24 hours. The sine qua non for successful pleurodesis is an apposition of the pleural surfaces. While the exact amount of apposition required for a successful pleurodesis is unknown, it is usual to attempt pleurodesis after at least 50 to 70% apposition is visible on frontal radiographs.[2] Suction may be applied if apposition does not occur; however, this is usually unnecessary and excessive use of suction may increase the risk of reperfusion edema. Lack of apposition may be due to a thick visceral peel ("lung entrapment"), pleural loculations, proximal large airway obstruction or a persistent air leak. If pleural loculations are evident, then thoracoscopic drainage and pleurodesis or image-guided drainage of loculi may be done followed by pleurodesis.

Presence of proximal airway obstruction is a relative contraindication for intercostal tube drainage (and pleurodesis; Fig. 159.2). Suction is attempted for incomplete lung expansion due to persistent air leak. When suction is applied, the use of high-volume low-pressure systems is recommended with a gradual increment in pressure to about -20 cm H_2O.[2] Mild sedation with midazolam is achieved just prior to pleurodesis with 3 mg/kg (21 ml of 1% solution for a 70 kg male, maximum of 250 mg) lignocaine instilled intrapleurally just prior to the sclerosant. This achieves good analgesia with safe peak serum levels of lignocaine.[55] The chemical sclerosant is then instilled in the pleural space either through an intercostal tube or during thoracoscopy with an atomizer, following complete drainage of the effusion. The intercostal drain is clamped for an hour after the procedure.

Choice of Sclerosing Agent

An ideal sclerosing agent must have high molecular weight and chemical polarity, low regional clearance, rapid systemic clearance, a steep dose-response curve and should be well tolerated with minimal or no side effects. The choice of a sclerosing agent will be determined by the efficacy, availability, safety, ease of administration, number of administrations to achieve a complete response and cost. Despite the evaluation of a wide variety of agents, to date no ideal sclerosant exists. The use of sclerosants increases the probability of successful pleurodesis [RR 1.20 (95% CI 1.04 to 1.38), based on five studies with a total 228 subjects].[56] Pleurodesis practices vary widely from region to region around the globe.[57]

When different sclerosants are compared, talc is the most effective with a RR of effusion nonrecurrence of 1.34 (95% CI 1.16 to 1.55,10 studies, N=308) in favor of talc compared with bleomycin, tetracycline, mustine or tube drainage alone.[56,58] Talc mediates pleurodesis by antagonizing intrapleural VEGF by endostatin induction.[59] Talc slurry is well tolerated and chest pain and fever are the most common side effects seen.[58] Several reports of fatal acute respiratory distress syndrome (ARDS, 1–9% incidence) occurring after talc pleurodesis, mainly from American centers, suggested that talc may not have a good safety-efficacy profile.[60] Review of experience with talc pleurodesis from rest of the world literature, however, suggests that this toxicity may be related to the use of talc preparations with particles <15 µm in size (N=558, 0% incidence of ARDS with graded talc).[61] The small particles may escape into the systemic circulation through the parietal pleural pores, causing a marked systemic inflammatory response and ARDS. When graded talc (small particles <10 µm removed) was compared to mixed talc (mean diameter <15 µm) in randomized trial (N=48), a greater increase in the A-a gradient, a decrease in the PO_2, an increase in the C-reactive protein and a higher incidence of fever was seen.[62]

In summary, graded talc as slurry or poudrage is the most widely used and the most effective agent for pleurodesis currently. Problems with use of medical talc in India include its unavailability, cost and need for appropriate sterilization prior to use. Sterilized commercial talc (face talc, Johnson and Johnson) which has been batch analyzed for impurities (asbestos) and particle size has been used for pleurodesis effectively during thoracoscopy[63] or as slurry in India. This is another acceptable option for pleurodesis provided that batch analysis and sterilization are ensured.

Iodopovidone is an iodine-based topical antiseptic. It is extensively absorbed from mucosal surfaces with a 100-fold increase in serum iodine concentration. Iodopovidone undergoes minimal metabolism and is excreted unchanged. Several series using iodopovidone have shown no evidence of clinically evident thyroid abnormalities,[64] but caution must be exercised in patients with pre-existing hypersensitivity or thyroid disease. A solution containing a mixture of 20 ml 10% iodopovidone and 80 ml normal saline (Microshield, Johnson and Johnson) through the intercostal drain is used to create pleurodesis.[65] A success rate of 64.2–100% [summary success of 90.6% (95% CI, 86.4 to 93.8%)] has been reported, comparable to talc.[64,66] Pain is the most common side effect observed. Iodopovidone has been widely used in India including at our center, is safe, cheap, effective and widely available. Given these advantages, iodopovidone is likely to become the agent of choice for medical pleurodesis in India. Larger studies are however required, given the current database is formed by six studies (including 265 patients) only.[67]

Tetracycline was widely used in the past; however, the production of parenteral tetracycline has ceased in most countries and this agent is no longer available in India for pleurodesis. Filtered oral forms of tetracycline (35 mg/kg) or doxycycline (10 mg/kg) re-constituted in saline produce pleurodesis and have the potential as safe, inexpensive and effective agents for pleurodesis.[68] Filtered oral tetracycline is used in some Indian centers as the first choice (personal communication), but published large studies on efficacy in humans is lacking.

Bleomycin is an antineoplastic agent used in pleurodesis. Its mechanism of action is predominantly as a chemical sclerosant similar to talc. Bleomycin has a success rate (defined as nonrecurrence of effusion) of about 60% (55 to 85%). The recommended dose is 60,000 units intrapleurally. Bleomycin is expensive and relatively ineffective compared to talc for achieving pleurodesis. Nitrogen mustard and mitoxantrone are other antineoplastic agents, which have been used for successful pleurodesis and are cheaper alternatives to bleomycin.

Silver nitrate causes caustic injury to the mesothelium and results in pleural adhesions and pleurodesis. Silver nitrate was one of the first agents used for pleurodesis in concentrations varying from 1 to 10% and has a success rate of 75 to 90%. Severe pain and large exudative effusions may complicate its use. Given its low cost and wide availability, there is an interest in the use of low-concentration (0.5%) silver nitrate for pleurodesis.[69]

Quinacrine is an antimalarial agent that has been used for pleurodesis in Scandinavian countries with a success rate of 64 to 100% (N= 98). Pain, fever, nausea and mental status changes are common and hence widespread use of this agent is unlikely.[70]

Dried killed *Corynebacterium parvum*, an anaerobic gram-positive bacterium, has been used for pleurodesis with an overall success rate of 76% (169 patients, nine publications). However, its availability is limited and is not used extensively for this indication. OK-432 is obtained from the SU strain of *Streptococcus pyogenes* and is both immune-stimulating and cytotoxic and has been used with success rate of 70 to 80%. It has been considered as the agent of choice in Japan.

The search for more effective and safe agents for pleurodesis is ongoing. Transforming growth factor-β is a unique cytokine with potent profibrotic as well as anti-inflammatory activity. It upregulates collagen production and does not cause any inflammatory pleural response in animal models. It appears to be a more effective pleurodesis agent than talc in animals and human trials are awaited.[71]

Thoracoscopic Poudrage versus Intercostal Tube Drainage and Pleurodesis

Thoracoscopic talc poudrage is more effective when compared to talc slurry with a relative risk of nonrecurrence of 1.19 (95% CI 1.04 to 1.36, two studies, N=112) in favor of thoracoscopic pleurodesis. However, the evidence-base of the superiority of talc poudrage is weak; several trials suggest that talc slurry is as efficacious as poudrage.[72,73]

Other Issues in Pleurodesis

Small bore drain (10 to 14 Fr) insertion is generally easier to perform, causes less discomfort to the patient and is equally effective as larger drains (24 to 32 Fr); therefore a small drain is the initial choice for effusion drainage and pleurodesis.[74,75] Traditionally, pleurodesis was performed once drain output was <150 ml/day and the lung is fully expanded. The chest drain is removed once the output is <150 ml/day post-pleurodesis. This leads to longer hospital stays and greater costs. Rapid pleurodesis involves placing a 9-14 Fr catheter under guidance, achieving complete drainage and then attempting pleurodesis immediately. Fluid drainage is monitored for 12 hours post-procedure and the pleural catheter is removed if fluid output is <100 ml; otherwise, a second pleurodesis is performed after 24 hours. If loculations or fluid reaccumulation is detected, sonographically guided thoracentesis and pleurodesis through the thoracentesis needle is performed. This has been shown to be effective and can be performed with small drains in <24 hours.[76,77] The amount and duration of fluid draining after sclerosant instillation does not indicate pleurodesis success,[78] and the length of stay is significantly reduced when the chest drain is removed at 24 hours (4 versus 8 days). In the absence of excessive fluid drainage (greater than 250 ml/day), the intercostal tube is removed within 24–48 hours of pleurodesis.

The use of rotation and position change to disperse sclerosants after instillation through the chest drain is not supported by evidence. Unlike mesothelioma, malignant seeding of biopsy sites and drain site is extremely uncommon in metastatic pleural effusions and routine radiation to these sites is not recommended.[2]

When loculated pleural effusion prevents complete drainage and pleurodesis, the choice of procedure depends on the patient's performance status. If the performance status is good, thoracoscopic drainage and talc pleurodesis is the procedure of choice. Surgical pleurectomy and pleurodesis is an alternative where thoracoscopy is not available, but is seldom done.[79] Another alternative in resource-constraint settings is fibrinolysis of multiloculated effusions, followed by pleurodesis.[80] There are no large studies at present to guide patient selection and judge outcomes with this intervention currently; however, multiloculated effusions with poor performance status and trapped lung in resource-constrained settings may be situations for this modality.[81]

LONG-TERM AMBULATORY PLEURAL DRAINAGE

Incomplete lung re-expansion due to a thick visceral pleural peel (lung entrapment) prevents pleural apposition and prevents successful pleurodesis. Unlike patients with "trapped lung", these effusions are exudative, associated with ongoing pleural malignancy or inflammation and may increase in size.[82] The best management option for this situation is the insertion of a tunneled pleural catheter. This is 15.5 F silicone rubber catheter, 66 cm in length, with fenestrations along the proximal 24 cm and is inserted into the pleural space using the Seldinger technique under local anesthesia. A one-way valve prevents air from entering and permits drainage into a vacuum bottle at regular intervals. When compared to doxycycline pleurodesis for recurrent symptomatic effusion, indwelling catheters have shorter hospital stays (1 versus 6.5 days), lesser late recurrences (13% versus 21%, P=0.446) and comparable improvement in dyspnea and the quality of life. Further, 46% (N=42) achieved spontaneous pleurodesis at a median of 26.5 days.[83] This initial experience has subsequently been confirmed by other authors. Malignant seeding of the tract and occurrence of infection are rare with appropriate care.[84] If the indwelling catheter is used as the first line of management,[85] patients with significant drainage after two weeks should be offered chemical pleurodesis through the catheter.[1]

PROGNOSIS

The predictors of survival in terms of decreasing importance include the performance status of the patient, the site of the primary lesion and the stage of malignancy. The performance status is significantly associated with mortality and the median survival is 1.1 months with a Karnofsky score <30 and 13.2 months with a score >70.[86] The median survival of a patient with MPE varies from 3 to 12 months, depending on the stage and the type of underlying malignancy; in general, this is shortest with carcinoma lung and longest with ovarian carcinoma.[87] As discussed above, poor correlation exists between biochemical characteristics (including pH) of pleural fluid and survival.

Malignant Pleural Mesothelioma

Arun S Shet, George D'Souza

INTRODUCTION

Mesothelioma is an insidious neoplasm arising from the mesothelial surfaces of the pleural and peritoneal cavities, the tunica vaginalis or the pericardium. Eighty percent of all cases are pleural in origin. The predominant cause of malignant mesothelioma is inhalational exposure to asbestos, approximately 70% of cases of pleural mesothelioma being associated with documented asbestos exposure. Due to limited availability of data based on which one can formulate evidence based guidelines, this chapter incorporates practical and updated guidelines on the management of mesothelioma. These guidelines are generally made on the basis of expert opinion unless otherwise stated in the text. For a discussion on peritoneal, pericardial and tunica vaginalis origin mesothelioma, the reader is directed to other sources in the literature.

EPIDEMIOLOGY

The incidence of mesothelioma in the United States peaked in the year 2000 is on the decline with an annual incidence estimated as approximately 3,300 cases per year. However, the incidence is increasing in many other places in the world, particularly in the Great Britain and Europe, where a peak of up to 2,450 deaths per year are expected around the year 2015. The incidence of mesothelioma in the more developed countries is falling due to recent legislation aimed at reducing asbestos exposure in the workplace and the general environment. On the other hand, mesothelioma incidence rates are predicted to increase dramatically in the less developed countries secondary to the poor regulation of asbestos mining and the proliferation of industrial and household utilization of asbestos.

The annual incidence of malignant pleural mesothelioma in India is now known. India imports nearly 100,000 metric tons of asbestos per year (2005 data), and small-scale asbestos (chrysotile and tremolite) mining and milling contributes nearly 5–10% of the total national usage.[1,2] More recent studies suggest that the consumption of asbestos in India has increased greatly (IBAN report) to approximately 300,000 tons per year (2007).

Risk Factors

Asbestos

Asbestos, a group of hydrated magnesium silicate fibrous minerals, have closely been linked with the epidemiology and natural history of malignant mesothelioma.[3,4] There are two major types of asbestos: (1) serpentine and (2) amphibole. Ninety percent of the asbestos currently used in the United States is the Canadian chrysotile, a serpentine fiber that is reportedly less carcinogenic.

There appears to be a dose-response relationship between asbestos exposure and mesothelioma. This is best illustrated by the cohort study of 4,659 people living in an Australian city that produced crocidolite asbestos but who did not directly participate in its mining or milling; the incidence of mesothelioma increased significantly with greater environmental exposure, based upon the neighborhood and duration of residence.[5]

Recent studies indicate that environmental, non-occupational exposure to asbestos can also contribute to an increased risk of mesothelioma. In certain rural areas in Turkey and Bulgaria, soil contains remarkably high levels of tremolite asbestos fibers, many cases of mesothelioma in these regions appear to be secondary to long-term non-occupational asbestos exposure.[6,7] A role for non-occupational exposure to asbestos was also supported by a study from California in which an increased incidence of mesothelioma was associated with proximity to naturally occurring asbestos deposits.[8]

Persons at high risk of mesothelioma can be identified by tracing the processing and commercial uses of asbestos. Workers with high levels of asbestos exposure include miners, millers and producers of asbestos products and laborers who install plumbing, boilers and heating equipment in ships, factories and homes. The risk extends to workers who may not handle asbestos directly but are in proximity to the material, such as carpenters, electricians, and welders in shipyards. Thus, clinicians evaluating suspected malignant mesothelioma patients should take a detailed exposure history emphasizing the period 20–50 years before diagnosis and including possible household contact exposure.

According to the United States Geological Survey, India was the third largest consumer of absestos (302,139 tonnes in 2007) after China and Russia. However, unlike Russia, both China and India are not signatories to the International Labour Organization asbestos convention. Thus, it is likely that there will be an increase in asbestos related lung injury including mesothelioma in these rapidly industrializing countries, both due to increased consumption of asbestos and to lack of regulations regarding its use. Based on a survey of asbestos exposed workers, clinical asbestos-related diseases-pleural changes, pulmonary fibrosis, bronchogenic carcinoma and diffuse malignant mesothelioma are expected to occur in workers from mining, milling and manufacturing as well as in those with secondary exposures to asbestos-containing materials, including construction and maintenance workers, users of asbestos-containing consumer products and the occupants of asbestos-containing buildings.[1] Thus, the increased consumption of asbestos in India will eventually lead to substantial morbidity and mortality of which a part will be due to malignant mesothelioma.

Radiation Therapy

Radiation therapy ionizing radiation to supradiaphragmatic fields is a likely risk factor for the subsequent development of mesothelioma, with a long latent period between the initial treatment and the diagnosis of the second malignancy. The data are more convincingly in favor of increased risk for patients with lymphomas[9,10] and testicular cancers[11] who have been exposed to radiation as opposed to radiated patients with breast cancer[12,13] where the data are somewhat more conflicting.

Viral Oncogenes

Several lines of evidence have implicated the Simian Virus 40 (SV40) as a cofactor in oncogenesis related to mesothelioma.[14] SV40 is an oncogenic virus in human and mammalian cell systems. Sequences of DNA of the virus have been found in lymphomas, brain and bone tumors and mesotheliomas. However, there is data suggesting that SV40 virus may have been a contaminant of injectable polio virus vaccines approximately 30–50 years ago and that the presence of this virus in tumors may not necessarily be causal. Thus the putative role of SV40 in mesothelioma is controversial and its ultimate role in viral oncogenesis remains somewhat unclear and unproven.

Nanomaterials

There is an increase in the use of nanomaterials in several industries. Data from animal models implicated carbon nanotubes in the development of peritoneal mesothelioma.[15] Thus, with an increasing use of the organic and inorganic nanoparticles substances, it is likely that we will see the development of nanomaterial related pulmonary disease even if there is no increase in mesothelioma in humans.

PATHOGENESIS

Mesothelial cells form the lining of the parietal and visceral pleura where they normally facilitate the free movement of the lung during the process of respiration. Any form of injury to these cells can result in proliferation that occurs in response to the release of local growth factors. Asbestos can induce changes in these cells by several processes that can ultimately lead to malignant proliferation (Fig. 160.1). One of these mechanisms is by irritation as a result of physical properties. The shape and ratio of length to width determine how deeply into the lung these fibers can penetrate and indirectly affects their likelihood of inducing cancer. This irritative process can span from pleural plaques to a frank mesothelioma like process. Similarly, asbestos fibers can pierce individual cells and cause rupture of the mitotic spindle apparatus disrupting mitosis, resulting in chromosomal damage to the cells. Another form of injury induced by asbestos is the production of reactive oxygen species, which causes oxidant stress and damage to DNA, proteins and lipids. Finally, asbestos can also induce phosphorylation of kinases, promoting cellular activation and proliferation.

Several features noted in the mesothelioma cell suggest that there are multiple pathways that lead to oncogenesis. For instance, mesothelioma cells exhibit dysregulated growth, increased expression of telomerase and loss of certain tumor suppressor genes (p16, p14, NF-2 Merlin). Additionally, there is evidence for an antiapoptotic phenotype, increased angiogenesis and matrix interactions along with the release of growth promoting cytokines that exert paracrine effects. Thus, the development of mesothelioma appears to be a culmination of several events that act in concert to produce the eventual clinical phenotype exhibited by patients with mesothelioma (Fig. 160.1).

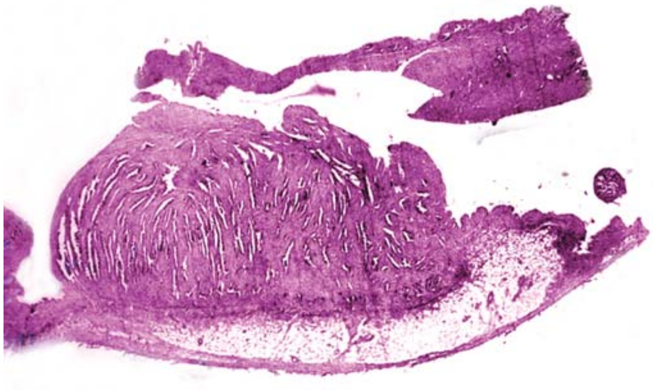

Fig. 160.1: Pleural nodule of mesothelioma situated perpendicular to the visceral layer of pleura [H & E x 100]

Pathology

Early stage MPM due to its slow growth can present as multiple small nodules that occur characteristically on the parietal pleura but can also involve the visceral pleura. Eventually, these nodules coalesce to form a thickened rind of tumor that fuses the parietal and visceral pleurae. At a more advanced stage, the tumor typically encases the entire lung and extends along the interlobar fissures resulting in a thick rind of tumor that can reach diameters of several centimeters or more, despite only minimal invasion of the underlying lung parenchyma. The consistency of the tumor can vary from firm to gelatinous. Adjacent structures can be involved at an early stage, with invasion of the chest wall, pericardium and diaphragm, and a majority of patients will have mediastinal lymph node involvement at autopsy (Fig. 160.2).

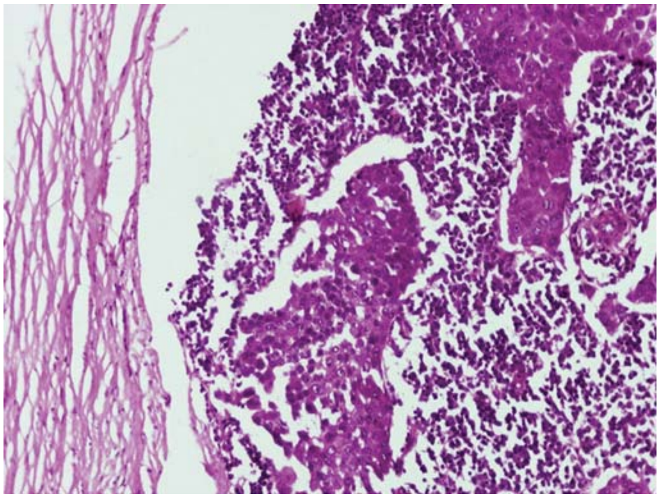

Fig. 160.2: Photomicrograph confirming the metastases of pleural mesothelioma in sinusoids of a cervical lymph node [H & E x 250]

Histologically, mesothelioma is typically classified into three broad histologic subtypes: (1) epithelioid; (2) sarcomatoid and (3) biphasic (mixed). The epithelioid variant is the most common, comprising about 60% of all mesotheliomas. Typical histological appearances of this subtype include tubulopapillary, acinar (glandular), adenomatoid and solid epithelioid patterns. In addition to reactive mesothelial hyperplasia, the differential diagnosis includes metastatic carcinomas and other epithelioid tumors. Sarcomatoid mesotheliomas are composed of malignant spindle cells, which may mimic malignant mesenchymal tumors, such as leiomyosarcoma or synovial sarcoma. Desmoplastic mesothelioma, which consists of bland tumor cells between dense bands of collagenous stroma, is considered to be a subtype of sarcomatoid mesothelioma (Fig. 160.3). In addition to fibrous pleurisy, the differential diagnosis includes sarcomatoid carcinoma and other sarcomas. Biphasic or mixed mesotheliomas have epithelioid and sarcomatoid features, but multiple tissue sections or larger samples may be needed to demonstrate both components.

There is no single marker that has sufficiently high sensitivity and specificity for malignant mesothelioma, and it is, therefore, standard practice for pathologists to employ a panel of markers (both positive and negative). Pancytokeratin stains are very useful in diagnosis and will stain the vast majority of mesothelioma. If the tumor is pancytokeratin negative, then the screening panel should

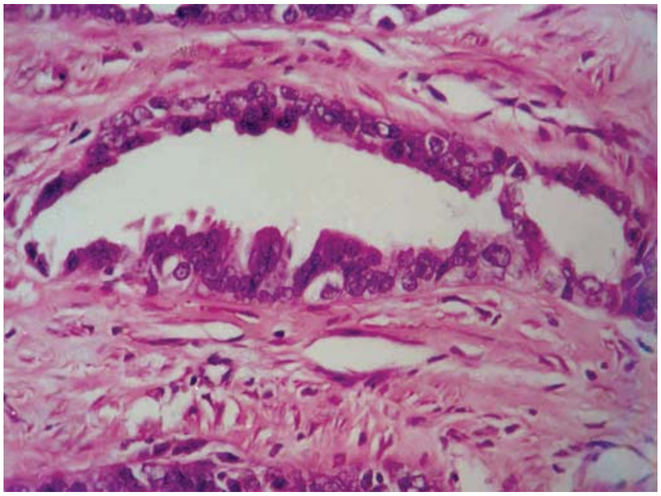

Fig. 160.3: Note the glandular epithelium of the neoplastic component sitting directly on the underlying stroma without the intervening basement membrane [H & E x 400]

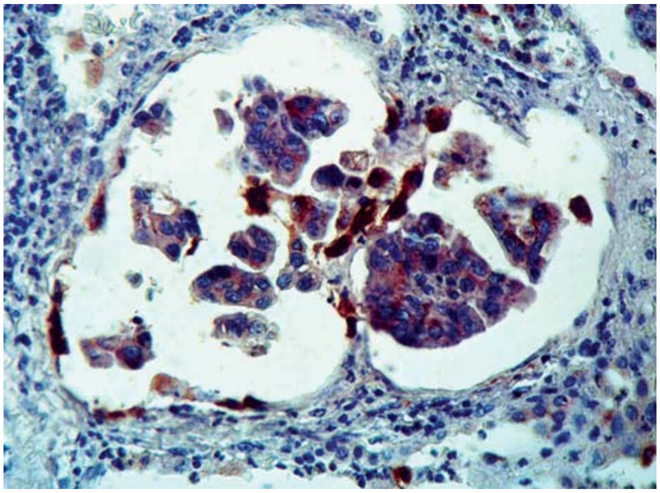

Fig. 160.4: Immunohistochemistry confirming the mesothelioma expressing positivity for calretinin [H & E x 400]

be broadened to include stains to exclude lymphoma, melanoma, angiosarcoma or epithelioid hemangioendothelioma. For epithelioid mesothelioma, common positive immunohistochemical markers that can be used to support a diagnosis of pleural mesothelioma include calretinin, CK5/6, the Wilms' tumor-I (WT1) antigen (nuclear staining) and D2-40 (podoplanin). For sarcomatoid or biphasic pleural mesothelioma cytokeratin reactivity does not necessarily differentiate malignant mesothelioma from other sarcomas, particularly if the cytokeratin staining is focal. Multiple cytokeratin antibodies, such as AE1/3, CAM5.2 (or CK 18) and CK7, should be used since cytokeratin expression can be focal, weak or variable. Electron microscopy, which used to be the gold standard for mesothelioma diagnosis, is now largely replaced by immunohistochemistry (Fig. 160.4).

Although the published literature has limited pathological series from India, single center experience from the pathology department at St. Johns National Academy of Health Sciences during 1969–1991 revealed a predominance of epithelial type mesotheliomas.[16]

CLINICAL PRESENTATION

Mesothelioma most commonly presents in the fifth to seventh decades of life. A large proportion of patients diagnosed at an earlier age have a history of childhood exposure to asbestos. The most frequent presenting symptoms of pleural mesothelioma are dyspnea and nonpleuritic chest pain. Rarely, asymptomatic patients present with a unilateral pleural effusion that is found incidentally on routine chest radiograph. Common physical findings at the time of diagnosis include unilateral dullness to percussion at the lung base, palpable chest wall masses and scoliosis toward the side of the malignancy.

The clinical presentation may also be accompanied by a variety of described paraneoplastic syndromes: (a) Disseminated intravascular coagulation; (b) Migratory thrombophlebitis; (c) Thrombocytosis; (d) Coombs-positive hemolytic anemia; (e) Hypoglycemia and (f) Hypercalcemia associated with secretion of a parathyroid hormone-like peptide. Several prognostic factors have been identified of which the retrospective review series by the surveillance, epidemiology and end results program of 1,475 patients including age, sex, stage, treatment and geopgraphical area of residence.[17] Based on these and other factors, prognostic scores have been developed and prospectively validated by both the Cancer and Leukemia Group B (CALGB) and the European Organization for Research and Treatment of Cancer (EORTC).[18–20] Several of these prognostic scores have served as the basis for the design of randomized controlled chemotherapy trials in good performance patients.[21] Often, the identification of these prognostic factors (Table 160.1) provides some guidance in determining the patient's eligibility for chemotherapy or best supportive care in a limited resource setting.

In general, the disease is staged using the TNM based Union Internationale Contre le Cancer (UICC) classification (Table 160.2), although the major drawback

TABLE 160.1: Factors indicating good or poor prognosis at the time of presentation

Factor	*Good prognosis*	*Poor prognosis*
Interval since diagnosis*	Symptoms < 2 months prior to diagnosis	Symptoms > 2 months prior to diagnosis
Age†	Age under 75 years	Age > 75 years

TABLE 160.2: TNM based Union Internationale Contre le Cancer (UICC) classification

TNM	
TX	Primary tumor not assessable
T0	No evidence of primary tumor
T1a	Tumor limited to ipsilateral parietal mediastinal, diaphragmatic pleura; no involvement of visceral pleura
T1b	Tumor involving ipsilateral parietal mediastinal, diaphragmatic pleura, with focal involvement of viscera pleural surface
T2	Tumor involving any of the ipsilateral pleural surfaces with one of the following: confluent visceral pleural tumor, invasion of diaphragmatic muscle or invasion of lung parenchyma
T3	Tumor involving any of the ipsilateral pleural surfaces with one of the following: invasion of the endothoracic fascia, invasion into mediastinal fat, solitary focus of tumor invading the soft tissues of the chest wall, or nontransmural involvement of the pericardium (locally advanced but resectable)
T4	Tumor involving any of the ipsilateral pleural surfaces, with at least one of the following: diffuse or multifocal invasion of soft tissues of the chest wall, any involvement of rib, invasion through the diaphragm to the peritoneum, invasion of any mediastinal organ, direct extension to the contralateral pleura, invasion into the spine, extension to the internal surface of the pericardium, pericardial effusion with positive cytology, invasion of the myocardium, invasion of the brachial plexus (locally advanced but unresectable)
NX	Regional lymph nodes not assessable
NO	No regional lymph node metastasis
N1	Metastases to the ipsilateral bronchopulmonary or hilar lymph nodes
N2	Metastases to the subcarinal or ipsilateral mediastinal lymph nodes
N3	Metastases to the contralateral mediastinal or internal mammary lymph nodes, or anysupraclavicular node metastasis
MX	Presence of distant metastases not assessable
M0	No distant metastasis
M1	Distant metastasis present

Stage grouping:

Stage I			
A	T1a	N0	M0
	T1b	N0	M0
B	T2	N0	M0
	T3	Any N	M0
Stage II	Any T	N1	M0
Stage III	Any T	N2	M0
	T4	Any N	M0
	Any T	NN3	M0
Stage IV	Any T	Any N	M1

of any staging system in MPM is the uncertainly in defining the T and N extent of disease by current imaging techniques. There are several staging systems including one that has been recently devised by members of the International Mesothelioma Interest Group which has been approved by the UICC. In the absence of any clear agreement as to which staging system is the most appropriate, it appears that the TNM based UICC classification is currently the most widely accepted standard despite the above mentioned limitations.

Natural History

Mesothelioma exerts its morbidity and mortality via inexorable local invasion. Patients typically develop shortness of breath and chest pain as the tumor gradually obliterates the pleural space and replaces any pleural fluid. As the tumor spreads, deoxygenated blood is shunted through the encased lung, leading to fatigue, dyspnea and hypoxemia that is often refractory to supplemental oxygen. Further growth of the tumor results in localized invasion and any of the following symptoms depending on the site of the original growth (dysphagia, hoarseness, cord compression, brachial plexopathy, Horner's or superior vena cava syndrome). While unusual, metastases may occur to the opposite lung, brain and other extrathoracic sites. Extension of the malignancy into the abdominal cavity may occur, particularly in patients who have prolonged survival after primary aggressive therapy of their thoracic disease, and spread throughout the abdomen in a manner similar to primary peritoneal mesothelioma may be observed. In such patients, invasion of liver and other organs is rare, but bowel obstruction can be a problem.

DIAGNOSTIC APPROACH

Malignant mesothelioma is often misdiagnosed initially and patients may be subjected to multiple consultations and tests before the correct diagnosis is established. Although thoracentesis or closed pleural biopsy often can establish the diagnosis of pleural malignancy, it may not provide enough tissue to distinguish mesothelioma from lung adenocarcinoma. Closed pleural biopsy is also not sufficiently reliable to define the histological subtype of mesothelioma, a potentially important factor in choosing therapy. In addition, negative results do not exclude a diagnosis of mesothelioma. Although rarely indicated, surgical intervention (via video thoracoscopic biopsy or open thoracotomy) has a higher diagnostic yield. In a study of 188 consecutive patients during 1970–1993, video-assisted thoracoscopic (VATS) biopsy was diagnostic in 98% of cases, compared with 26% for thoracentesis alone and 39% for fluid cytology and closed pleural biopsy.[22] For an approach to patients with MPM, the algorithm given in Fig. 160.5 is a good starting point. Most patients presenting to our institution with MPM present with advanced disease and do not have good performance scores. Thus, a majority may not go through a complete three step assessment for the role of multimodality therapy (Fig. 160.6). Instead, based on the presence or absence of certain prognostic markers, we would elect for chemotherapy or best supportive care based on the performance score.

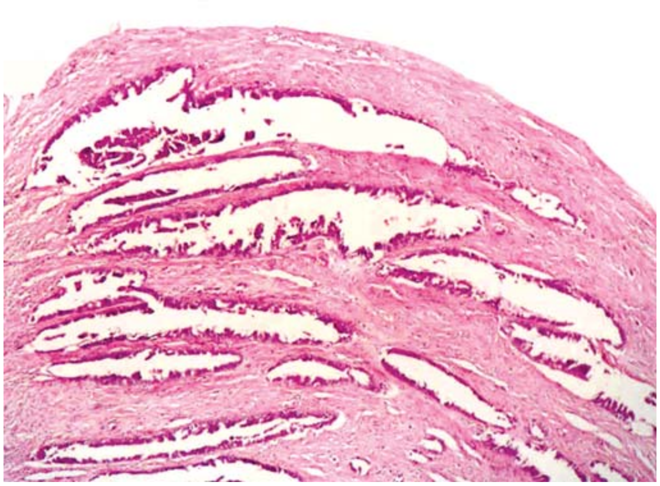

Fig. 160.5: Classical presentation of the glands at right angles to the underlying pleura [H & E x 250]

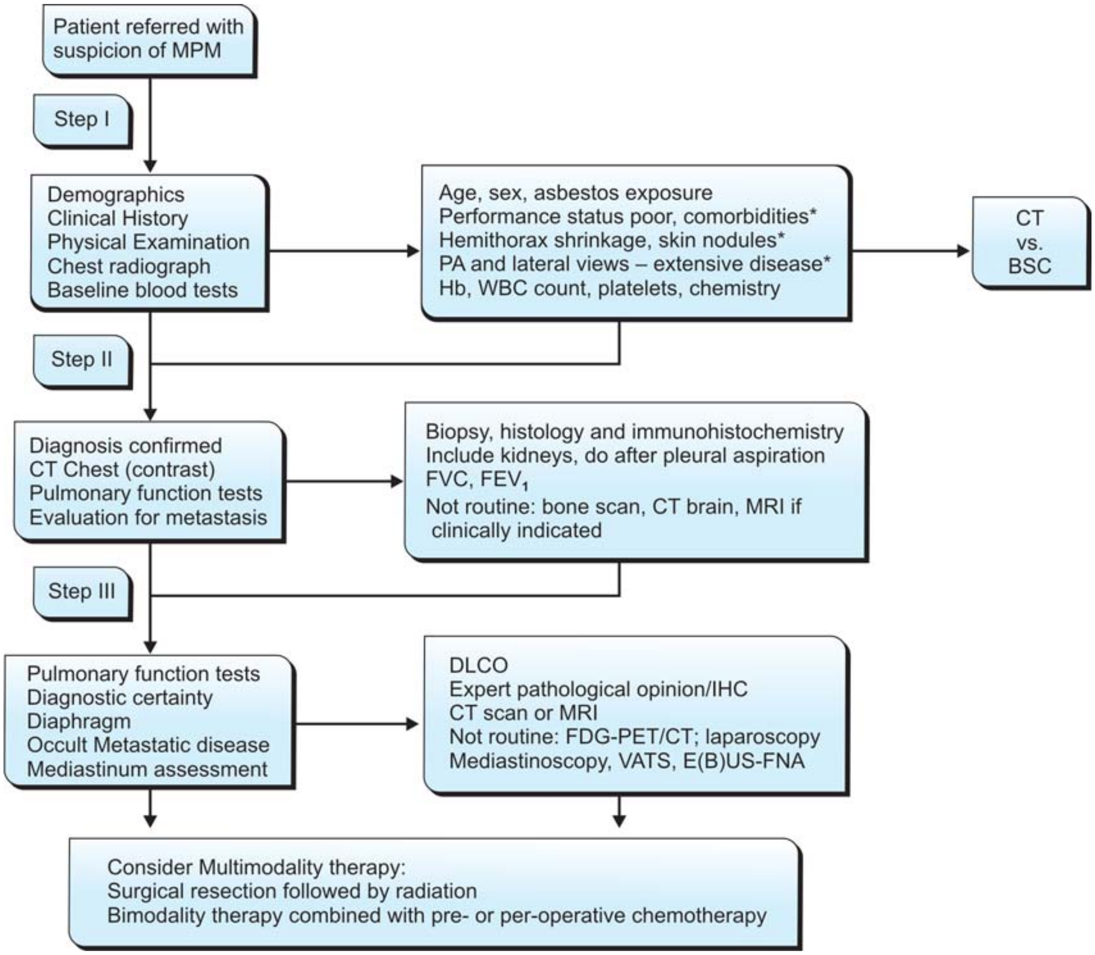
Cytopathological and Histopathological Diagnosis

Once a sample of pleural fluid or tissue is obtained, a group of immunohistochemial markers is important in diagnosing malignant mesothelioma. Malignant mesothelioma is characterized by the presence of staining for EMA, calretinin, WT1, cytokeratin 5/6, HBME-1 (an anti-mesothelial cell antibody) or mesothelin (more than 85% of epithelioid mesotheliomas). The absence of staining for certain markers (carcinoembryonic antigen; thyroid transcription factor-1; the tumor glycoproteins B72.3, MOC-31 and Ber-EP4; and the epithelial glycoprotein BG8) is particularly useful in narrowing down the differential diagnosis.

Tumor Markers

A role for tumor markers has not yet been well established in mesothelioma although several markers



Patient referred with suspicion of MPM
Step I
Demographics
Clinical History
Physical Examination
Chest radiograph
Baseline blood tests
Age, sex, asbestos exposure
Performance status poor, comorbidities*
Hemithorax shrinkage, skin nodules*
PA and lateral views – extensive disease*
Hb, WBC count, platelets, chemistry

FVC, FEV1
Not routine: bone scan, CT brain, MRI if clinically indicated
Step III
Pulmonary function tests
Diagnostic certainty
Diaphragm
Occult Metastatic disease
Mediastinum assessment
DLCO
Expert pathological opinion/IHC
CT scan or MRI
Not routine: FDG-PET/CT; laparoscopy
Mediastinoscopy, VATS, E(B)US-FNA
Consider Multimodality therapy:
Surgical resection followed by radiation
Bimodality therapy combined with pre- or per-operative chemotherapy

Fig. 160.6: Approach to malignant pleural mesothelioma (MPM)
*Indicates reasons to consider best supportive care (BSC) or chemotherapy (CT)

have been assessed in the past. Two recently identified serum biomarkers that appear to have a potential include Serum Mesothelin Related Protein (SMRP) and osteopontin.[23,24] The SMRP levels are elevated in 84% of patients with malignant mesothelioma compared with less than 2% in patients with other pulmonary or pleural diseases. These markers may have utility as an adjunct to cytopathological or histopathological diagnosis but currently are not available as clinical tools in our setting.

TREATMENT

Surgery

Surgery for malignant pleural mesothelioma can be diagnostic, palliative, or rarely, curative in intent. The vast majority of patients have locally advanced disease, advanced age or other comorbid medical illnesses, precluding aggressive surgical intervention. Thus, surgical intervention for potential cure is only possible in a small percentage of patients with localized disease. Additionally, less than 25% of those eligible for aggressive surgical intervention will be alive at five years, and even fewer will be disease-free. Although associated with substantial morbidity, surgery has resulted in palliating the major symptoms of the disease, although a survival benefit has been seen in selected patients.

Pleurectomy and extrapleural pneumonectomy have been used to try to definitively treat the primary tumor, although neither of these approaches has been shown to increase survival. These procedures can be considered in patients to obtain symptom control, especially for lung entrapment syndrome. However, both of these procedures are associated with substantial morbidity, and thus should be performed only at centers with considerable experience.[25]

In general, the consensus is that surgery, whether debulking or radical resection, is best performed in conjunction with other forms of treatment (chemotherapy and radiotherapy or other investigational therapy).[26] Among surgically treated patients with MPM, the only long-term survivors have undergone extrapleural pneumonectomy as part of multimodality therapy.[27] Operative mortality is approximately 5% for radical surgery in experienced centers[28] but morbidity is 50%.

Pleurodesis

By far, the most common and bothersome symptom in mesothelioma is persistent dyspnea from large, unilateral pleural effusions. A reasonable palliative approach is complete drainage of the pleural effusion (by tube thoracostomy or video thoracoscopy) and introduction of an irritative agent into the pleural space (by injection or insufflation) to produce pleurodesis.

Instillation of agents (tetracycline, doxycycline, bleomycin, talc), pleurectomy, pleuroperitoneal shunting and radiation are other treatments that have been described for malignant pleural effusions. The general recommendations for pleurodesis are to use sterile talc and perform this procedure early in the course of disease. A simple and cheap option for pleurodesis, which is widely available, is to use the solution of povidone iodine mixed with 10% lidocaine and 100 mg hydrocortisone. Our experience shows that this is an effective and inexpensive approach to manage resistant pleural effusions. Thoracoscopic application (poudrage) may be more successful than other methods of pleurodesis (e.g. by tube thoracostomy), because of the presence of bulky tumor or “trapping” of the lung by a thick visceral pleural peel of tumor which compromises the efficacy of pleurodesis.

Chemotherapy

Although previously results of chemotherapy were disappointing and survival rates less than 10 months, the appearance of several new antineoplastic agents has resulted in improvements in objective response rates and overall survival.[29] Evaluation of the effectiveness of chemotherapy requires adequate definitions of response. Both the objective response rate (as measured on CT scan by a decrease of greater than 30% in the thickness of the pleural rind perpendicular to the rib cage) and progression-free survival have been used as surrogates for efficacy in all the phase III studies to date in MPM patients.

Single Agent Chemotherapy

Cisplatin, gemcitabine, permetrexed, anthracycline, vinca alkaloids have all been shown to have substantial activity in the setting of phase II studies; however, cisplatin is the most active single agent and forms the back bone for combination chemotherapy regimes.

Combination Chemotherapy

Three randomized clinical trials have established that platinum-based dual agent chemotherapy significantly prolongs survival compared to single agent chemotherapy or best supportive care.[20,29,30]

Permetrexed/cisplatin: In the single-blinded EMPHACIS trial, 456 patients were randomly assigned to cisplatin (75 mg/m^2) plus either permetrexed (500 mg/m^2) or a placebo, both given once every three weeks. The median survival was significantly longer for the combination (12.1 vs 9.3 months), as was the time to progression (5.7 vs 3.9 months) and the objective response rate (41% vs 17%). All parameters favored the combination therapy group, including global quality of life, pain, dyspnea, fatigue, anorexia and cough. In a multivariate regression analysis of prognostic factors derived from this trial, factors predictive of overall survival were therapy group, vitamin supplementation group (those receiving both B12 and folic acid), Karnofsky performance status (90–100 vs 70–80), less advanced disease stage, non-mesothelioma histological subtype and white blood cell count (≥ 8200/µL vs lower values). Permetrexed/carboplatin combination has been studied in the phase II setting and appears to have similar efficacy compared with permetrexed/cisplatin and can be used in the setting where cisplatin nephrotoxicity is a concern.

Raltrexed/cisplatin: The efficacy of this combination was studied in a phase III trial in which 250 patients were randomly assigned to raltitrexed (3 mg/m^2) plus cisplatin (80 mg/m^2, both in 21 day cycles) or the same dose of cisplatin alone. In the 213 patients with measurable disease, the combined therapy group had a higher objective response rate. Survival in all randomized patients was significantly increased with the combination regimen: the median survival was 11.4 versus 8.8 months with single agent and the one-year survival was 46 versus 40%. Thus, first line combination chemotherapy including cisplatin and pemetrexed or raltitrexed demonstrates greater activity than cisplatin alone in phase III studies, with higher response rates and improved survival. Any combination of this doublet-based chemotherapy is currently considered the standard therapy for first line treatment of MPM.

Although the scientific rationale for chemotherapy and the evidence base supporting such therapy has been conclusively demonstrated in the setting of randomized controlled trials, the utility of such chemotherapy may be questioned in a limited resource setting where patients pay out of pocket. Furthermore, despite statistically significant improvement in overall survival, in the setting of limited resources, whether such marginal improvements in survival offer any meaningful value to the patient is something that may need to be assessed sensitively by both patient and physician. Overall, a very careful evaluation of the socioeconomic status, overall performance status and patient willingness for chemotherapy may help further delineate patients that would benefit most from chemotherapy.

Second Line Chemotherapy

Several second line agents have been shown to have a response in the setting of mesothelioma that is unresponsive to primary combination chemotherapy. The available data are rare (only 6 phase II studies) and do not allow for the proposal of any specific agent or schedule. In our setting we tend to recommend best supportive care for such patients, as they tend to have a Karnofsky performance status of less than 70 once they have failed first line therapy. Exceptionally well preserved patients in whom financial status does not impact treatment decisions may elect to undergo salvage therapy in which case our most preferred agent is permetrexed or vinorelbine.[31] Ideally, such patients should be enrolled in a clinical trial to assess the role of such therapy in a scientific manner.

Radiotherapy

Malignant mesothelioma is traditionally resistant to radiotherapy.[32] Furthermore, the diffuse nature of the tumor prevents localized radiation therapy. However, local radiotherapy can be delivered to surgical sites with questionable margins or to prevent seeding of tumor and can also be used to palliate symptoms. Fractionated radiotherapy using intensity modulation is the technique that has shown some success and is generally used after surgical resection of malignant melanoma. Other radiotherapeutic approaches have also been tried but the results have been disappointing.

Novel Approaches

Molecularly targeted therapies (thalidomide,[33] bevacuzimab, geftinib,[34] imantinib,[35] and erlotinib[36]), immunotherapy (interferon and interleukins[37]), and gene therapy have been investigated with varying but limited degrees of success. Most of these therapies have not yielded dramatic results although with the small numbers that have been studied assessment of results tends to be somewhat conflicted. In general, such treatments should be attempted only in the setting of a clinical trial.

Palliative Therapy

Recurrent pleural effusions are best controlled by the removal of all fluid, with the use of suction when required, followed by chemical or surgical pleurodesis. There are several types of pain in patients with malignant mesothelioma. Local involvement of the chest wall causes somatic pain. Intercostal nerve or vertebral invasion causes neuropathic pain. Organ invasion causes more diffuse visceral pain. Opiates typically provide adequate pain relief for the duration of action of the drug (4 hours for liquid morphine and 12 hours for sustained-release morphine). Special attention should be paid to initiating patients on medications that prevent constipation.

Somatic pain often responds to a nonsteroidal anti-inflammatory drug given in addition to an opiate. In general we used paracetamol before going to more effective non-steroidal anti-inflammatory agents such as naproxen. The cycloxygenase 2 (etoricoxib) inhibitors are especially useful and have little or no side effects. Neuropathic pain requires the addition of an anticonvulsant, such as carbamazepine, gabapentin or sodium valproate. Some patients require procedural pain relief, such as intrathecal analgesia or nerve block however, in our setting this is not commonly an approach that is taken. Palliative radiotherapy aimed at pain relief may be considered in cases of painful chest wall infiltration or nodules.

Dyspnea due to fluid accumulation or encasement of the lung by tumor is common. Typically this is difficult to treat and can be addressed using a combination of therapies including blood transfusions (anemia), diuretics (fluid overload), centesis (effusion), and oxygen. Other measures that have been shown to be helpful in the setting of lung cancer,[38] such as creating a stream of air across the face, self help breathing techniques and yoga, may be tried.

Psychosocial factors are important in the palliation of malignant mesothelioma. In the setting of limited resources, it is especially important to pay attention to palliative care provided in the form of a team of doctors and non-medical staff including, surgeons, chest physicians, oncologists, pain and palliative care specialists, psychologists and physiotherapists to ensure that this occurs in a timely and meaningful manner.

Prevention

A key method of prevention of cancer in general is population based screening to detect disease at an early stage and improve prognosis by more effective medical or surgical treatment. This would seem like an attractive strategy in mesothelioma where the time to develop invasive cancer seems to be at least a decade, if not more. To date however, the inadequate performance of potential screening methods[39] and the low prevalence of disease do not seem to justify large scale screening programs.

Aside from screening, public health policy related to occupational health exposures in limited resource countries needs to improve to reduce the potential future burden of asbestos related illness including mesothelioma.[2] Several issues may need to be resolved before prevention of mesothelioma becomes a reality in the Indian setting. For instance, the occupational exposure standard is still 2 fibers/ml of air (compared to the United States occupational safety and health administration guidelines: 0.2 fibers/ml of air for fibers >5 µm in length). The Health and Safety Legislation Act does not cover 93% of workers in the unorganized sector where asbestos exposures are extremely high and workers remain uninformed and untrained in dealing with asbestos exposure. Furthermore, mesothelioma is not recognized as an occupational disease in India and the latest cancer registry data have no information on mesothelioma.[2] Industrial hygiene assessment is seldom carried out and pathologists do not receive training in identifying mesothelioma histopathologically. Greater awareness and advocacy among health care professionals and public health policy experts may enforce changes that result in prevention as a better strategy than cure.

Criteria to Consider Multimodality Therapy

1. Biopsy proven non-sarcomatoid MPM
2. Clinical stage T1-3, N0-1, M0
3. Patients fit for pneumonectomy (adequate cardiovascular reserve)
4. Patients with good performance status (fit to receive chemotherapy)
5. Patients fit to receive radical hemithorax radiation

ACKNOWLEDGEMENT

The authors are grateful to Dr Usha Kini, Department of Pathology, for providing histopathological images to reproduce for this chapter.

Pulmonary Involvement in Collagen Vascular Disease

Om P Sharma

INTRODUCTION

Collagen vascular diseases can involve any part of the thorax including the lung parenchyma, pleura, airways, blood vessels, lymph nodes, lymph channels, chest wall musculature and the diaphragm. In these multisystem disorders, the lung involvement can be a part of the multisystem illness or it may be the only manifestation of the systemic illness. Occasionally, the lung involvement may herald the onset of the systemic illness. In most cases, however, the pulmonary involvement is detected during the course of the collagen vascular illness. The following discussion encompasses important pulmonary manifestations of the principal collagen vascular diseases (Table 161.1).

TABLE 161.1: Key facts of thoracic involvement in collagen vascular disease (CVD)

1. Any part of the thorax can be affected by collagen vascular disease.
2. Thoracic manifestations may precede, occur concurrently or follow the course of collagen vascular disease.
3. Thoracic manifestations of CVD may be indistinguishable from secondary infections and toxicities caused by the drugs used for treating CVD.
4. Rheumatoid arthritis-related lung disease is more common in men.
5. Thromboembolism frequently occurs in systemic lupus erythematosus patients.
6. Malignancy may complicate the course of scleroderma and dermatomyositis; lymphoma may occur in the patients with Sjogren’s syndrome.
7. A normal chest X-ray does not exclude parenchymal lung disease; lung functions and High Resolution Computed Tomography (HRCT) are often required.
8. Smoking exacerbates collagen vascular disease and alveolar hemorrhage.

RHEUMATOID ARTHRITIS

Rheumatoid Arthritis (RA) is a systemic autoimmune process that primarily affects the joints, and can also involve other organs, including the lungs and pleura, eyes, skin, heart and peripheral nerves. Pleuropulmonary disease is more common in the patients with RA who have severe chronic articular disease, high titers of rheumatoid factor, subcutaneous nodules, cutaneous vasculitis, myopericarditis, ocular inflammation and Felty’s syndrome. Pleuropulmonary abnormalities associated with the rheumatoid process are many and the differential diagnosis is wide[1,2] (Table 161.2).

Pleural Involvement

Pleural involvement can cause pleural effusion, empyema, chylothorax, pleural thickening, fibrothorax and lung entrapment. Autopsy studies have reported pleural disease in 38 to 73% of the patients with rheumatoid arthritis; however, only 2 to 21% patients with pleural disease have symptoms and only 5% have radiological evidence of pleural inflammation.[3-5] Pleural effusion can be caused by inflammation or by necrosis, cavitation and rupture of a nodule into the pleural space. Pleural disease has a remarkable predilection for men, although RA is more common in women in a ratio of 2:1 to 3:1. Pleural involvement mostly remains sub-clinical or asymptomatic. When symptoms occur, dyspnea, fever and chest pain are most common. Physical examination may reveal a pleural friction sound and diminished breath sounds over the affected lung field.

TABLE 161.2: Pulmonary complications of rheumatoid arthritis

Tissue involved	*Manifestation*
Pleura	Effusion Empyema Pleural thickening Calcification Pneumothorax
Parenchyma	Necrobiotic nodules Caplan's syndrome Pneumonitis Interstitial fibrosis Bronchiolitis Obliterans Organizing Pneumonitis (BOOP) Apical bullous disease
Airways	Airway obstruction Bronchiolitis Bronchiectasis
Blood vessels	Vasculitis Pulmonary hypertension
Thoracic muscle cage	Dyspnea, muscle weakness

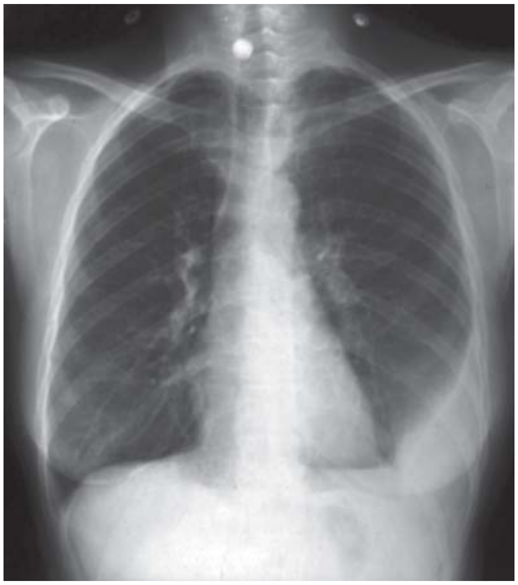

Fig. 161.1: A left-sided pleural effusion in a woman with rheumatoid arthritis for more than ten years. Pleural fluid glucose was 20 mg/ml. She was asymptomatic. No treatment was given

Thoracentesis should be performed in patients who have RA and a pleural effusion. Pleural fluid analysis usually reveals a white cell count less than 5,000/mm^3, a pleural fluid glucose of less than 0.3 g/L, a pleural fluid glucose to serum glucose ratio less than 0.5, a pH less than 7.3 and high pleural fluid LDH level (i.e. > 700 IU/L). Low glucose levels are nonspecific and may occur in tuberculosis and malignant mesothelioma. Less commonly, patients with RA and a long-standing pleural effusion may develop cholesterol effusion, known as a pseudochylous or chyliform effusion. Cholesterol effusions have the appearance of an empyema, but are sterile. The milky appearance is due to an elevated cholesterol level (always >65 mg/dL and sometimes over 1000 mg/dL); cholesterol crystals, identifiable with polarized light, may also be present. Cytological examination of rheumatoid pleural fluid often reveals slender or elongated or round multinucleate macrophages and giant multinucleated cells and ragocytes or "RA cells".[6,7]

Rheumatoid pleuritis and pleural effusions commonly resolve spontaneously (Fig. 161.1). The reported useful treatment options include Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), glucocorticoids (oral or intrapleural), pleurodesis and decortication. When treatment is required due to the presence of pleuritic chest pain or the size of the effusion, the initial choice is an NSAID, such as indomethacin. In refractory cases of pleural effusion, a moderate dose of oral glucocorticoids, e.g. 10-20 mg of prednisone daily, may be beneficial. If the patient is intolerant of the side effects due to systemic glucocorticoids, intrapleural glucocorticoids, e.g. 120-160 mg of depo-methylprednisolone acetate can be tried. Use of chemical pleurodesis and decortication is reserved for refractory effusions and fibrothorax.

Interstitial Lung Disease

In Walker's series comprising of 516 cases, only 8 (2%) had radiographical evidence of Interstitial Lung Disease (ILD).[3] A much higher prevalence is detected by pulmonary function testing. As many as 41% of patients with RA have restrictive impairment and reduced diffusion capacity.[8] High resolution computed tomography can identify the clinically silent lung disease. A higher prevalence of ILD occurs in men then in women. Other risk factors include smoking, high titers of RF, alpha-1 anti-trypsin variants, subcutaneous nodules and prominent joint manifestations.[9] Diffuse pulmonary fibrosis of RA has features similar to those seen in Idiopathic Pulmonary Fibrosis (IPF) patients. However, the rheumatoid pulmonary fibrosis is a separate entity, because the lungs of these patients, in addition to the usual changes of IPF, show specific features of hyaline collagen nodules, often with necrosis, along with a surrounding palisade of fibroblasts[10-12] (Fig. 161.2).

The symptoms of rheumatoid ILD are nonspecific, namely: dyspnea, dry cough and basal lung crepitations. Finger clubbing may also be present.

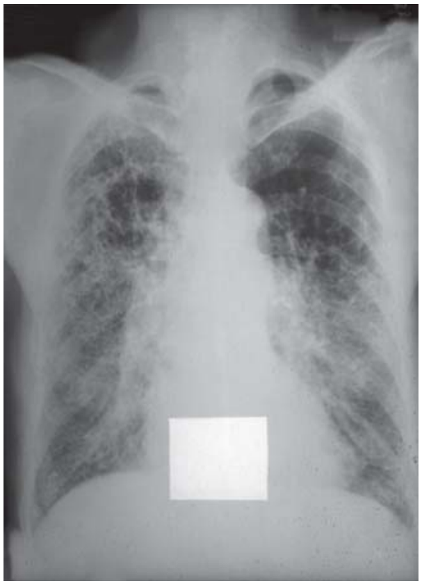

Fig. 161.2: Posteroanterior view of the chest in a patient with rheumatoid arthritis showing extensive interstitial disease with honeycombing and cystic changes

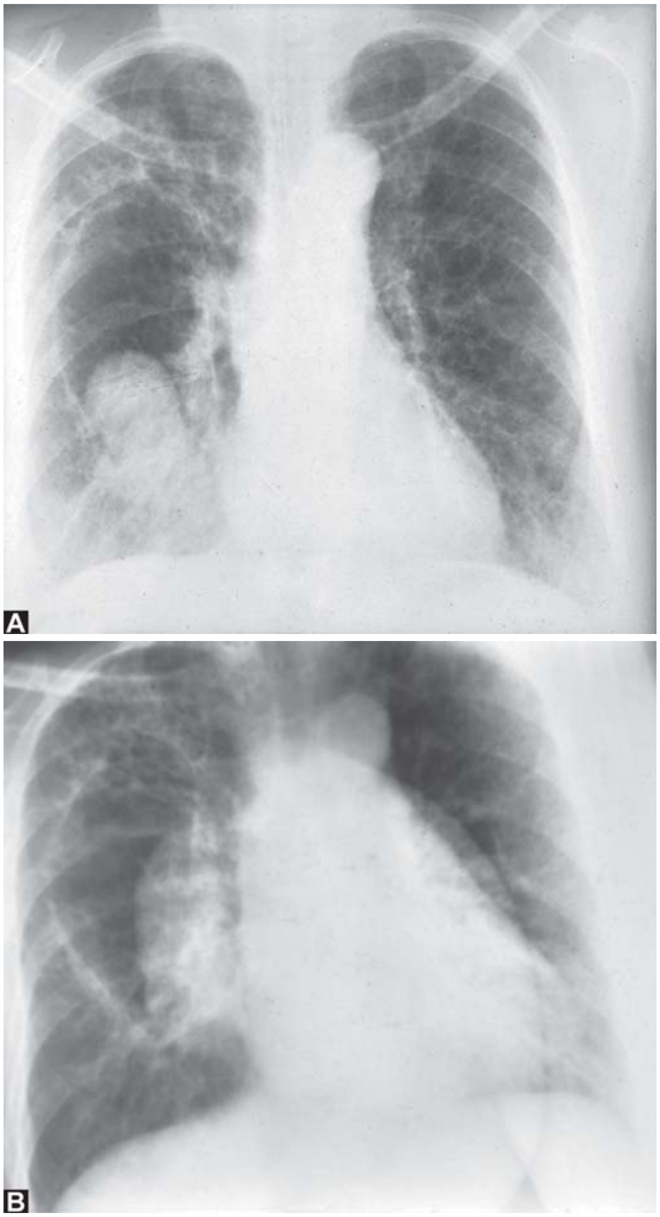
In established cases, chest X-ray films show small lungs with diffuse bilateral reticulonodular infiltrates with lower lobe predominance. Progression of the disease results in cystic spaces, honeycombing and fibrosis. HRCT of the chest shows similar lesions, but with higher sensitivity.[13] Erythrocyte Sedimentation Rate (ESR) is usually raised and serum rheumatoid factor is positive (Figs 161.3A and B).

Rheumatoid ILD has a better prognosis and slower rate of deterioration than IPF. Spontaneous remission can occur. No optimal therapeutic approach has been established for RA related ILD. Often corticosteroids are used as the first-line treatment. Initial dose of prednisone is 1 mg/kg per day for 6-8 weeks with subsequent tapering based on clinical and lung function monitoring. Response to corticosteroids is variable. Drugs, like methotrexate, azathioprine, cyclophosphamide, have been used alone and in combination with prednisone. Cyclosporine has been proved beneficial in selected cases. Bronchoalveolar Lavage (BAL) fluid lymphocytosis indicates a good response to treatment, whereas BAL neutrophilia portends a poor prognosis.[13]

Rheumatoid Nodules

Rheumatoid nodules are the specific pulmonary manifestation of RA. The prevalence of pulmonary rheumatoid nodules is not clear. In one series, only 2 of 516 patients showed radiological evidence of nodules.[3] However, a study of open lung biopsies from 40 patients with suspected lung disease found that rheumatoid nodules were the most common abnormality present in 13 patients; 8 out of these 13 patients had multiple nodules[10] (Figs 161.4 and 161.5). There are two types of rheumatoid lung nodules: Intrapulmonary necrobiotic nodules and Caplan's syndrome.



Figs 161.3A and B: A posteroanterior and right decubitus chest X-ray films showing a large cavity and with an aspergilloma. The patient has history of rheumatoid arthritis for more than 40 years

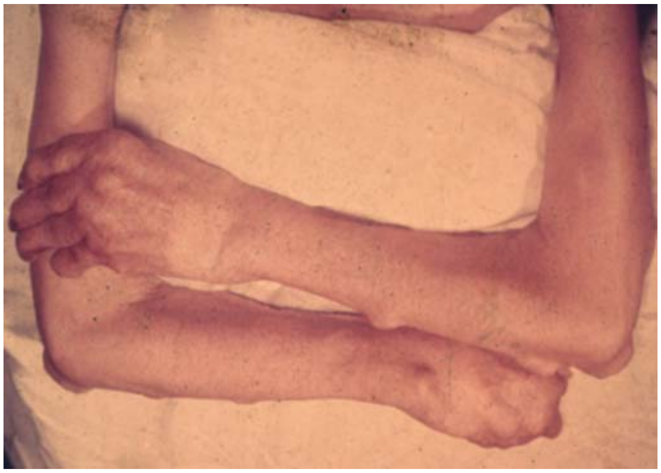


Fig. 161.4: A 60-year old man with advanced rheumatoid arthritis and many subcutaneous nodules. He has high rheumatoid factor titer. He is the type of rheumatoid arthritis patient who is prone to developing pulmonary nodules and interstitial fibrosis

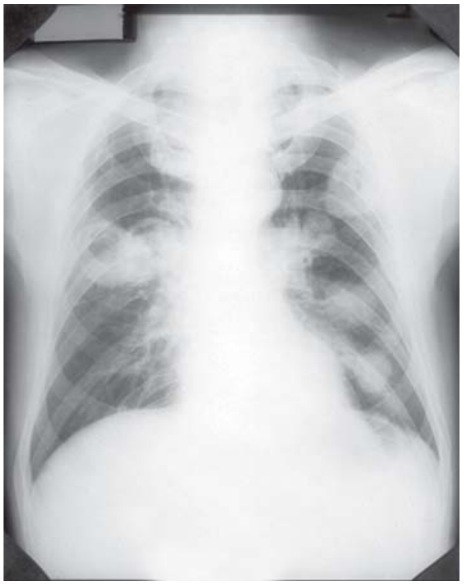

Fig. 161.5: A posteroanterior view of the chest of a patient with rheumatoid arthritis showing multiple solid and cavitary pulmonary nodules

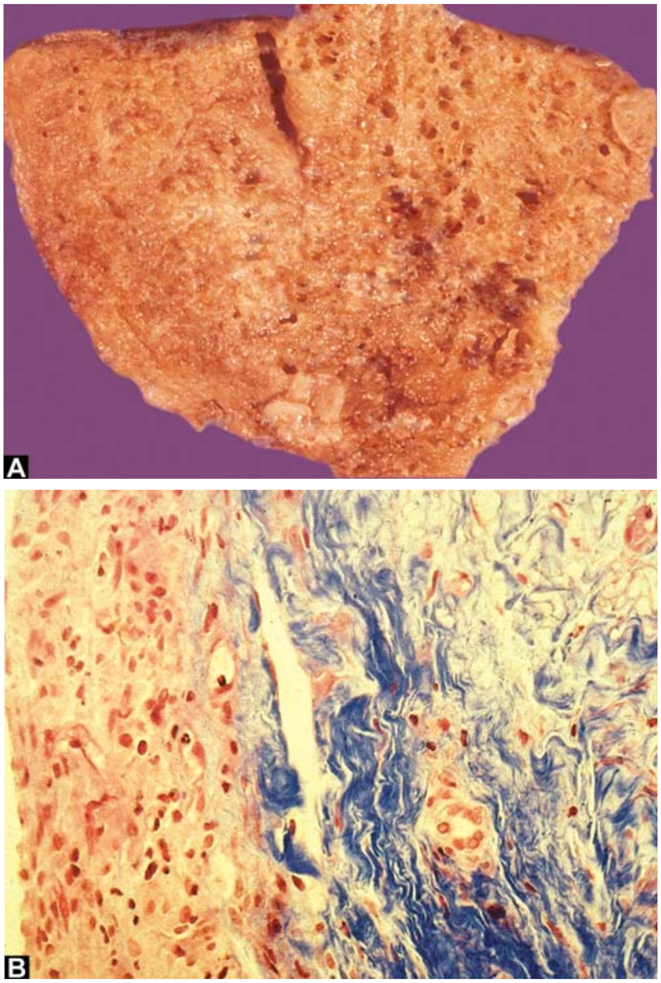
Necrobiotic Nodules

These may occur in any part of the lung, but are generally frequent in subpleural areas and in association with interlobular septa. The histology of a rheumatoid pulmonary nodule is similar to that of rheumatoid nodules at other sites, with central necrosis, palisading epithelioid cells, a mononuclear cell infiltrate and vasculitis. These nodules may shrink, disappear, cavitate or become fibrotic. The prognosis is good (Figs 161.6A and B).



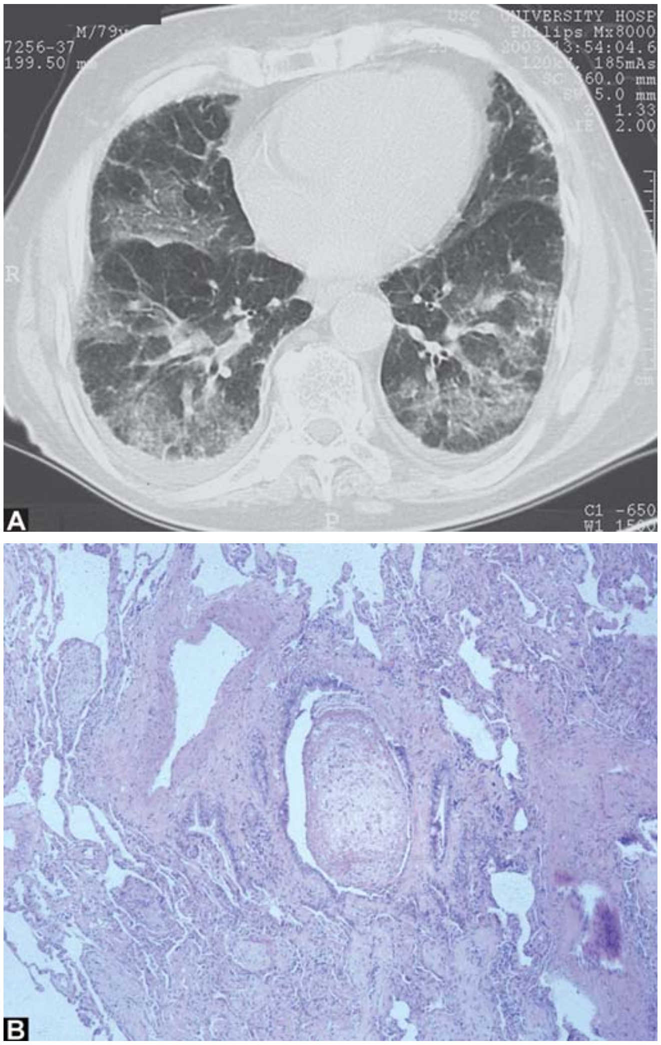
Figs 161.6A and B: (A) Gross appearance of rheumatoid pulmonary nodules; (B) Histolgical appearance with palisading inflammatory cells and fibrosis in a rheumatoid nodule

Caplan's Syndrome (Rheumatoid Pneumoconiosis)

In 1953, Caplan first reported the occurrence of lung nodules in coal miners who also had rheumatoid arthritis. Caplan's syndrome can also occur in patients with RA exposed to both asbestos and silica. Histologically, the findings are similar to necrobiotic nodules, but are surrounded by pigmented cells. There is no effective treatment for Caplan's syndrome. The prognosis is good.[14]

Organizing Pneumonia

Organizing Pneumonia (OP), also known as BOOP or Cryptogenic Organizing Pneumonitis (COP) is a proliferative bronchiolitis. In a study of open lung biopsies from 40 patients with parenchymal lung disease and RA, OP was the second most common pathological



Figs 161.7A and B: (A) A CT showing peripheral and lower lobe patchy infiltrates characteristic of bronchiolitis obliterans organizing pneumonia (BOOP). It can occur in any collagen vascular disease; it responds nicely to treatment. (B) A lung biopsy showing typical Mason bodies causing obstruction of BOOP (HE X 100)

manifestation, following rheumatoid nodules.[10] In other series it was the most common ILD after Usual Interstitial Pneumonitis (UIP) and Nonspecific Interstitial Pneumonitis (NSIP).[11, 12] Patients with RA complicated by OP present with cough, dyspnea, malaise, weight loss and fever. Crackles are noted on physical examination. Diagnosis may occasionally be made with a transbronchial lung biopsy, but more commonly an open or thoracoscopic lung biopsy is required. The biopsy demonstrates patchy intraluminal polypoid plugs of immature fibroblast tissue within respiratory bronchioles (Figs 161.7A and B).

The prognosis of OP is generally good, but spontaneous improvement is rare. Most patients with OP respond rapidly to oral glucocorticoid therapy. Therapy with prednisone is usually initiated with 1-1.5 mg/kg per day (using ideal body weight) to a maximum of 100 mg/day given as a single oral dose in the morning for 4-8 weeks. If the patient becomes stable or is improved, the prednisone dose is gradually tapered to 0.5-1.0 mg/kg per day (using ideal body weight) for another 4-6 weeks. Prednisone is gradually tapered to zero if the patient remains stable or is improved after 3-6 months. The patient should be monitored with chest radiographs and pulmonary function testing every 6-8 weeks during the first year, and therapy should be reinstituted aggressively at the sign of any recurrence.

If the patient cannot tolerate corticosteroids, cyclophosphamide (1-2 mg/kg per day given as a single daily dose) is recommended. Start with 50 mg daily and slowly increase the dose over 2-4 weeks, not exceeding 150 mg/day. A trial of 3-6 months is usually required.

Airway Obstruction

Upper Airway Obstruction

Upper airway disease is more common in women and in patients with long-standing RA. Direct laryngoscopy and CT scanning demonstrate that 54 to 75% of patients have cricoarytenoid abnormalities. A rheumatoid nodule on the vocal cord or vasculitis involving the recurrent laryngeal or vagus nerves may cause obstruction. Early symptoms of upper airway disease may include a hoarse voice, odynophagia, tenderness of the throat and pain on coughing or speaking. Diagnosis of upper airway obstruction is made by laryngoscopy and inspiratory and expiratory flow volume loops.

Small Airway Obstruction

The prevalence of small airway obstruction and bronchial hyper-responsiveness in patients with RA remains unestablished, because studies have been confounded by the presence of smoking or RA-ILD. In non-smoking subjects, a prevalence of 0 to 24% has been reported.

Obliterative Bronchiolitis

Obliterative bronchiolitis (OB) is a rare and usually fatal condition characterized by progressive concentric narrowing of membranous bronchioles. An OB is more common in women patients with positive rheumatoid factor test and Sjögren's syndrome (Fig. 161.8). It can also occur in patients with RA who receive d-penicillamine, gold and sulfasalazine treatment. Patients typically present with the rapid onset of dyspnea and dry cough.

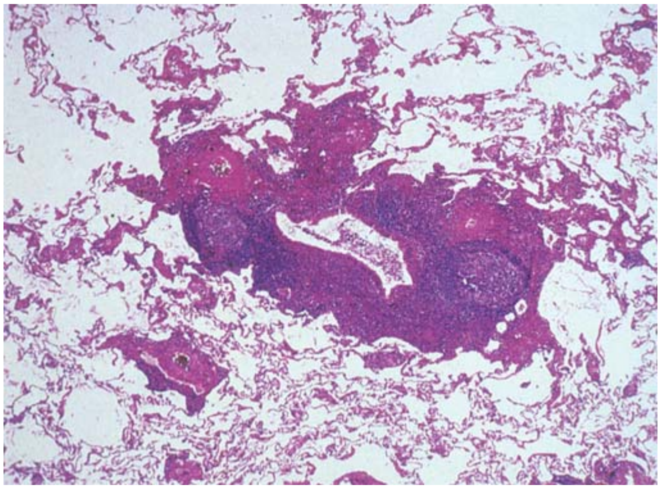


Fig. 161.8: Rheumatoid bronchiolitis (HE X120)

Fever, weight loss and malaise are generally not present. Physical examination may reveal inspiratory crackles and a mid-inspiratory squeak. Lung function changes include airflow obstruction, normal Diffusing Capacity of the Lung for Carbon Monoxide (DLCO) and hypoxemia. A trial of high dose corticosteroids, prednisone (in the dosage of 1-1.5 mg/kg per day) is indicated.[15,16]

Bronchiectasis

Although an association between bronchiectasis and RA has been noted, it does not appear to be clinically significant in most patients.[17]

Apical Bullous Disease

Apical fibrotic and cavitary lesions similar to those in ankylosing spondylitis have been reported in patients with RA.[18]

Thoracic Cage Involvement

Abnormalities of thoracic cage mobility, similar to those seen with ankylosing spondylitis, can occur.

Pulmonary Hypertension

Pulmonary arterial hypertension is rare in patients with RA. Its clinical manifestations and prognosis are similar to those with idiopathic pulmonary arterial hypertension in the absence of RA. Secondary pulmonary hypertension usually associated with severe ILD has also been reported in patients with RA.[19]

Lung Cancer

The risk of developing lung cancer may be slightly greater in patients with RA than in the general population.[20,21]

TABLE 161.3: Pulmonary complications of progressive systemic sclerosis (SSc)

Common

1. Non-specific interstitial pneumonitis
2. Usual interstitial pneumonitis/fibrosis
3. Pulmonary hypertension
4. Alveolar cell carcinoma
5. Pleural thickening

Uncommon

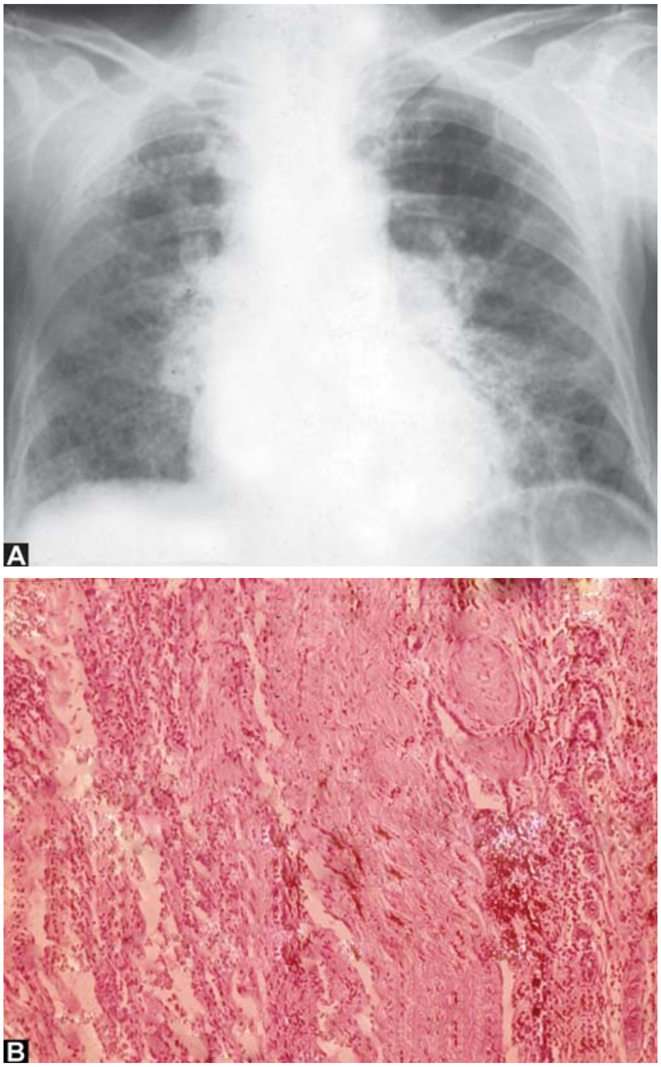
1. Pleural effusion
2. Pneumothorax
3. Bronchiectasis
4. Lung cancer
5. Vascular aneurysm

SCLERODERMA

More than 80% of patients with systemic sclerosis have lung involvement. ILD and pulmonary hypertension are the two major pulmonary complications. Other less common pulmonary complications include pleural effusions, aspiration pneumonia, spontaneous pneumothorax, bronchiectasis, hemoptysis, drug-induced pneumonitis and lung cancer[22,23] (Table 161.3).

Interstitial Lung Disease

The reported prevalence of ILD in patients with SSc varies. ILD is detected early by HRCT and in autopsy series. The early development of ILD occurs in African-American patients and in the patients with skin disease, high serum CPK levels, hypothyroidism and cardiac involvement.[24] Early SSc-ILD frequently causes no symptoms. When present, the most common symptoms are fatigue, breathlessness and dry cough. Chest pain is infrequent; hemoptysis is rare. The most characteristic physical sign is presence of bilateral fine inspiratory crackles rales at the lung bases. The symptoms, physical findings and radiographic characteristics of SSc-associated ILD are similar to other types of ILD.[25,26] The classic radiographic features of established ILD comprise of symmetric, reticular opacities. These are usually most pronounced at the lung bases (Figs 161.9A and B). Thin section (3 mm or less) HRCT scanning of the lung can demonstrate the character and distribution of fine structural abnormalities not seen on chest radiographs[27] (Fig. 161.10). The extent of ILD seen on HRCT, inversely related to Forced Vital Capacity (FVC) is a predictor of survival. The FVC is reduced and there is a proportional reduction of the Forced Expiratory Volume in One Second (FEV_1). The FEV_1/FVC ratio remains normal. The Total Lung Capacity (TLC), Functional Residual



Figs 161.9A and B: (A) Posteroanterior chest X-ray film showing difuse fine nodular and honeycombing in an adult with progressive systemic sclerosis; (B) Lung biopsy specimen from the patient shows extensive fibrosis

Capacity (FRC) and residual volume (RV) are decreased in ILD. The patients with SSc who have a near-normal FVC at initial presentation have low-risk for progression to severe lung disease. Diffusion capacity is reduced in over 70% of the patients and its decrease correlates with the severity of ILD seen on HRCT. A reduction in DLCO accompanied by relatively normal spirometry and lung volumes suggests pulmonary vascular disease. The value of the Six-Minutes Walk Test (6MWT) is more limited in SSc, as it does not discriminate well between patients with lung involvement and those without.[28]

The common pathological patterns of SSc-associated ILD are NSIP and UIP. The most frequently noted histopathological finding on lung biopsy in SSc is fibrotic NSIP. Intimal thickening of pulmonary arteries and resulting luminal narrowing is often found in post-mortem lung specimens. Lung biopsy is rarely indicated in SSc associated lung disease.[29,30]

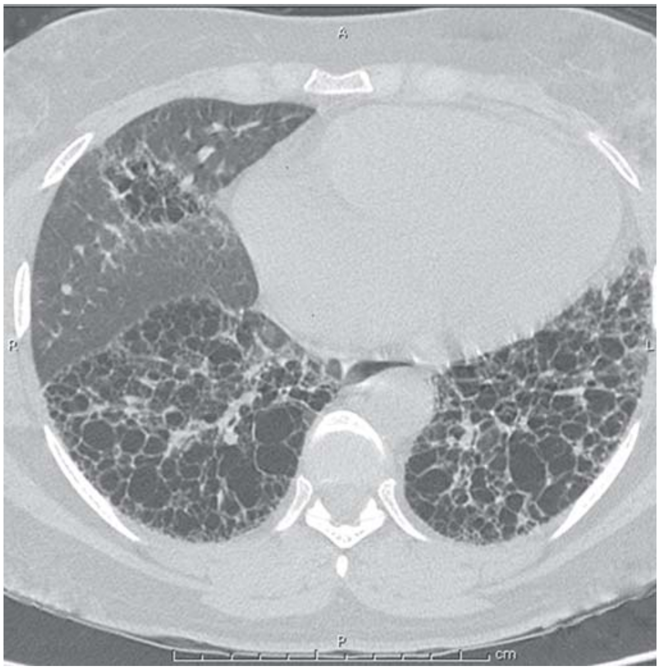


Fig. 161.10: HRCT showing honeycombing and dilated esophagus in a scleroderma patient

Bronchoalveolar lavage fluid in patients with SSc-associated ILD shows increased numbers neutrophils, eosinophils, lymphocytes and mast cells. The clinical significance of these findings is controversial. In a study of 158 patients with early SSc-associated ILD, there was no difference in the change in FVC after 12 months when patients with BAL-defined alveolitis were compared to patients who had a normal BAL. The levels of KL-6, a glycoprotein, found predominantly on type II pneumocytes and alveolar macrophages are elevated in the serum of patients with SSc-associated ILD.[31]

Pulmonary Arterial Hypertension

The prevalence of PAH in SSc varies 7 to 50%. It may occur as an isolated pulmonary complication of SSC, or can coexist with ILD. It may also be associated with the CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly and telangiectasias). Early PAH is asymptomatic, but dyspnea on exertion is the most common initial symptom. Patients with advanced PAH may have chest pain due to right ventricular angina, and near-syncope or syncope on exertion due to reduced cardiac reserve. On physical examination, advanced PAH may be associated with a prominent a-wave in the jugular venous pulse, a loud pulmonic second heart sound, and a right ventricular gallop. The murmur of tricuspid regurgitation is common and may be accompanied by a palpable right ventricular lift or heave.[32]

On a chest radiograph, PAH produces an enlarged pulmonary artery and attenuation of the smaller pulmonary vessels. The presence of PAH may be suspected if pulmonary function tests show a significant decrease in DLCO (less than 65% of the predicted value) in the presence of normal spirometry.[33]

Doppler echocardiography permits estimation of pulmonary artery pressures when tricuspid regurgitation is present. The test cannot be relied upon to exclude PAH in high-risk patients due to its limited sensitivity and technical limitations. Right heart catheterization is the gold standard for identification and evaluation of PAH.[34]

A new screening test for PAH in SSc is measurement of serum levels of Brain Natriuretic Peptide (BNP) and/or N-terminal pro-brain natriuretic peptide (NT-proBNP). Elevated NT-proBNP levels have a sensitivity and specificity of 90% respectively for the presence of PAH.[35-37]

Aspiration Pneumonitis

Gastroesophageal reflux, present in most patients, may cause recurrent aspiration of gastric contents and lung injury.[38]

Pleural Disease

Pleural effusion and spontaneous pneumothorax are rare complications.[39,40]

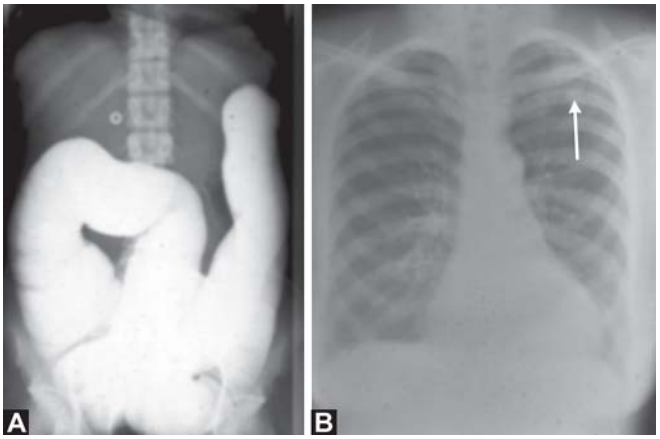
Bronchiectasis

Cylindrical bronchiectasis is a common finding on HRCT scanning of the lungs of patients with SSc. In one study comprising 22 patients, bronchiectasis was present in 59% of cases.[41,42]

Lung Cancer

The risk of lung cancer is increased in SSc patients with diffuse skin involvement (Figs 161.11A and B).

Corticosteroids have no effect on the course of established ILD in scleroderma. Colchicine suppresses the release of fibroblast growth factors *in vitro* from alveolar macrophages, but does not affect the scleroderma lung disease. Cyclophosphamide significantly improves dyspnea and lung functions.[43,44]



Figs 161.11A and B: A rare complication of pulmonary fibrosis in scleroderma. The patient has smooth colon. Because of the loss of haustral markings. There is a small lung nodule in the left upper lobe which on biopsy turned out to be an alveolar cell carcinoma

SJÖGREN'S SYNDROME

Sjögren's syndrome (SS) is characterized by lymphocytic infiltration of the lacrimal and salivary glands. It can exist as a primary disorder or as a secondary condition associated with other autoimmune diseases such as rheumatoid arthritis, Systemic Lupus Erythematosus (SLE) and scleroderma. The typical symptoms of SS are dryness of the eyes (keratoconjunctivitis sicca) and dryness of the mouth (xerostomia).[45]

Primary Sjögren's syndrome (pSS) primarily affects women between 50 and 70 years of age. The prevalence of pulmonary disease in SS has not been established, and the reported incidences vary greatly. In one study the prevalence of respiratory disease in patients with pSS was found to be as high as 75%.[46]

An ILD, the most common lung abnormality in SS, occurs in about 25% of all patients. It is particularly seen in patients who have both glandular and extraglandular features of SS. The most common type of ILD in pSS is NSIP[47] (Table 161.4).

Dyspnea and dry cough are two principal symptoms; the presence of bibasilar crackles is the most frequent sign. Asymptomatic patients can have detectable abnormalities on pulmonary function testing or HRCT. The chest radiograph may be normal, or may show a fine reticular or nodular pattern with basilar prominence on

3. Thin-walled cysts

chest radiograph in 10 to 20% of cases. The HRCT is more sensitive than chest radiograph for interstitial disease[48-50] (Table 161.5).

In patients with interstitial opacities on chest radiograph, pulmonary function tests commonly reveal a restrictive pattern with a low diffusing capacity.[49] The combination of a restrictive defect and a low DLCO appears to be more common in pSS than in sSS. Anti-Ro antibody positive patients have significantly lower diffusing capacity than anti-Ro antibody negative patients.[51]

In patients without clinical or radiographical evidence of pulmonary disease, BAL may show evidence of inflammation. A pure lymphocytic alveolitis is common; neutrophil predominance is also observed in some cases. A wide spectrum of histological changes, including a mild inflammatory response, NSIP, end-stage fibrosis, honeycombing and OP, is seen. A feature common in SS is lymphocytic infiltration causing follicular bronchiolitis, LIP, nodular lymphoid hyperplasia and lymphoma. Occasionally, in SS, lung biopsy specimens may reveal noncaseating granulomas, a finding suggestive of sarcoidosis.[52-54]

The treatment of SS and ILD remains empiric, since no controlled studies have been performed. In symptomatic patients with SS and ILD and functional deterioration, the standard treatment is oral prednisone in the dosage of 1 mg/kg per day with subsequent tapering, continued for at least six months. The patients who do not improve with systemic glucocorticoids should receive azathioprine, cyclophosphamide and cyclosporine.[55,56]

SYSTEMIC LUPUS ERYTHEMATOSUS

During the course of their illness, most patients with SLE show signs of pulmonary involvement (Table 161.6). Chest pain, cough, and dyspnea are often the first symptoms. Pleural inflammation may cause chest pain in the absence of a friction rub or radiographic evidence of a pleural effusion. The pain is often aggravated by deep breaths and change of position. Chest pain may also arise from the inflamed muscles and the connective tissue.[57]

Pleural Disease

The effusions, when present, are small, recurrent and often bilateral. The pleural fluid is an exudate with elevation of pleural fluid LDH. The total white cell count is low and pleural fluid glucose concentration is only slightly lower than serum blood levels. The complement levels and protein concentration are characteristically low in lupus effusions. Pleural disease and pain in SLE generally responds well to local heat, NSAIDs and topical analgesics. If there is no response within a few days, moderate to high dose steroids will generally be effective. Immunosuppressive agents are rarely indicated. Fibrothorax and lung entrapment are rare.[58,59]

Acute Lupus Pneumonitis

Acute lupus pneumonitis occurs in 1 to 12% of the patients and is characterized by fever, cough (sometimes with hemoptysis), chest pain, dyspnea, basilar rales and pulmonary infiltrates especially in the lower lung fields. Pleural effusion is present in about 50% of the patients.[60] Pathological examination in lupus pneumonitis reveals

acute alveolar wall injury, alveolar hemorrhage, alveolar edema, hyaline membrane formation and immunoglobulin and complement deposition (Table 161.7). The diagnosis of alveolitis may be made by the presence of late inspiratory crackles, and abnormalities on CT scanning, 67 gallium scintigraphy or BAL (Table 161.8). It is difficult to clinically separate acute lupus pneumonitis from alveolar hemorrhage. An increased DLCO is suggestive of alveolar hemorrhage. Video-assisted thoracoscopic biopsy or open lung biopsy may be necessary. The patients with lymphocytosis on BAL have the best prognosis, whereas, the predominance of eosinophils or neutrophils in lavage fluid portends high mortality rate. Lupus pneumonitis developing in the postpartum period has a poor prognosis.[61,62]

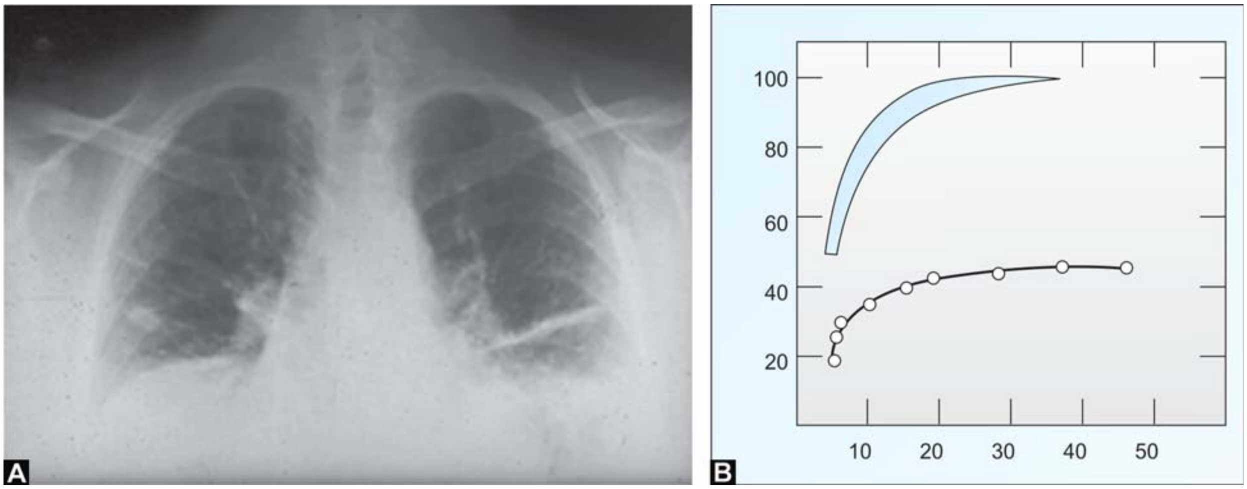
Acute lupus pneumonitis, however, needs prompt and aggressive treatment with prednisone around 1-1.5 mg/kg per day in divided doses. If no response is seen within 72 hours, the administration of intravenous pulse glucocorticoids (one gram of methylprednisolone per day for three days) and addition of slower acting immunosuppressive drugs, such as cyclophosphamide, should be considered.[63]

Chronic Lupus Pneumonitis

Chronic (fibrotic) lupus pneumonitis occurs in less than 10% of patients with longstanding SLE, and those with anti-Ro antibodies are more likely to develop chronic pneumonitis. These patients frequently suffer from chronic non-productive cough, dyspnea and recurrent pleuritic chest pain. Pulmonary function studies show a restrictive pattern with reductions in lung volumes, DLCO and arterial blood oxygen tension.

Chest radiographs reveal changes of chronic pneumonitis. The HRCT, BAL and 67-gallium scintigraphy are the important tools to diagnose lupus pneumonitis. In undiagnosed cases, lung biopsy may become necessary (Figs 161.12A and B).

Treatment of chronic lupus pneumonitis is begun with oral prednisone in a dose of 1 mg/kg per day. Patients treated with glucocorticoids tend to improve slowly and stabilize with time. Symptomatic improvement may not always be reflected in DLCO improvement. Immunosuppressive agents are considered if no



Figs 161.12A and B: (A) A chest X-ray film showing small lungs and linear basilar atelectasis in a patient with systemic lupus erythematosus. (B) The lung function graph shows reduced lung compliance

6. Type-II pneumocyte hyperplasia

response is seen within a few months of beginning steroid therapy. The optimal choice of immunosuppressant is uncertain, but cyclophosphamide, azathioprine or mycophenolate have all been utilized.[64,65]

Pulmonary Hypertension

Mild-to-moderate pulmonary hypertension occurs in more than 50% of the patients. Dyspnea, chest pain and chronic nonproductive cough are the frequent symptoms. Fatigue, weakness, palpitations and edema may also occur. Physical findings are similar to pulmonary hypertension from any other cause (Table 161.9). Laboratory abnormalities include hypoxemia, enlarged pulmonary arteries with clear lung fields on chest radiography, reduced lung volumes and a reduced carbon monoxide diffusing capacity and electrocardiographic evidence of right ventricular hypertrophy. The typical histopathological features of lupus-induced pulmonary hypertension include plexiform angiomas, thickening of the muscular wall of the pulmonary arteries, and immunoglobulin and complement deposition in the arterial walls.[66,67]

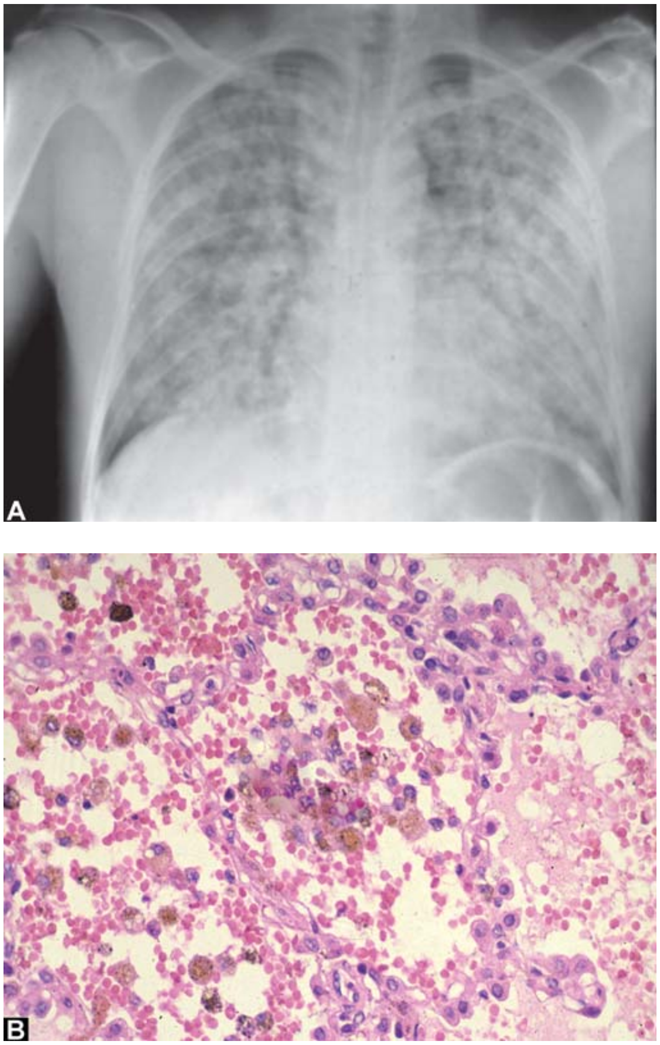
The management of patients with secondary pulmonary hypertension and SLE is similar to that in idiopathic pulmonary arterial hypertension.

Vanishing Lung Syndrome

This syndrome is characterized by dyspnea, pleuritic chest pain and a progressive decrease in lung volume without any significant lung or pleural disease on chest CT. The most likely cause of VLS is a myositis or myopathy that affects the diaphragms. However, some patients with VLS may have normal diaphragmatic muscle strength. The syndrome should always be considered in patients with SLE who have dyspnea, clear chest X-rays, and elevated diaphragms. Corticosteroids, theophylline, and/or immunosuppressive therapy may improve symptoms and pulmonary function.[68]

Pulmonary Hemorrhage

Alveolar hemorrhage is uncommon complication in SLE. Rarely, it may be the presenting manifestation of SLE, but most commonly it occurs during the course of an already diagnosed lupus.[69,70]



Figs 161.13A and B: (A) A chest X-ray film showing diffuse alveolar densities in a patient with SLE and hemoptysis. The patient was anemic and had an elevated single-breath diffusing capacity for carbon-monoxide; (B) A bronchoscopic biopsy in alveolar hemorrhage shows only blood and the test is of little value

The patient complains of dyspnea, hemoptysis and cough. Chest X-ray films may reveal bilateral alveolar infiltrates. Pulmonary magnetic resonance imaging may suggest hemorrhage, since the paramagnetic effects of iron in hemorrhagic blood result in preferential T2 shortening. The BAL yields bloody fluid with hemosiderin-laden macrophages. A significantly elevated diffusing capacity for carbon monoxide may be strongly suggestive of pulmonary hemorrhage; the diagnosis can be established definitively by lung biopsy.

High dose corticosteroids, cyclophosphamide, plasmapheresis, antibiotics and mechanical ventilation have improved survival rate (Figs 161.13A and B).

Cryptogenic Organizing Pneumonia (COP)

The COP (also known as BOOP) is a pathological entity characterized by the formation of plugs of fibrous tissue in bronchioles and alveolar spaces. Dry cough and multiple infiltrates on chest X-ray are two main clinical features. The diagnosis is confirmed by lung biopsy. Treatment with oral prednisone (1 mg/kg per day) is usually effective.[71]

Acute Reversible Hypoxemia

Acute hypoxemia as a manifestation of SLE is characterized by hypoxemia, a normal chest radiograph, and no evidence for pulmonary emboli. Plasma C3a levels are markedly elevated. In addition, up-regulation of adhesion molecules, such as E-selectin, VCAM-1 and ICAM-1, occurs suggesting that there is excessive complement activation and leukocyte-endothelial cell adhesion and leuko-occlusive vasculopathy. Glucocorticoids alone or with aspirin are effective.[72]

Pulmonary Veno-occlusive Disease (PVOD)

Pulmonary venoocclusive disease, a rare cause for pulmonary hypertension seen in SLE, is characterized by intimal fibrosis, occlusion of the pulmonary veins and edema in the interlobular septa. High resolution CT shows thickened interlobular septa, lymph node enlargement and ground glass opacities.[73]

Adult Respiratory Distress Syndrome

When Adult Respiratory Distress Syndrome (ARDS) develops, it is commonly due to bacteremia or sepsis with gram negative bacilli and more likely occurs in those who had been treated with glucocorticoids. It has a poor prognosis.[74]

DERMATOMYOSITIS (DM) AND POLYMYOSITIS (PM)

Four principal types of lung disease have been described in DM-PM[75,76] (Table 161.10).

Interstitial Lung Disease

When sought systematically in all patients, using techniques such as HRCT of the chest, the prevalence of ILD is about 40% in DM-PM. Several histological patterns of ILD occur in DM-PS[77,78] (Table 161.11).

Patients with ILD typically present with dyspnea and a nonproductive cough, fever and arthralgias.[64] Chest auscultation usually reveals dry bibasilar crackles. ILD can precede the diagnosis of myositis by months or years, or be the predominant feature at the time of presentation. The course of ILD varies amongst different patients (Table 161.12). In patients with symptomatic ILD, the pulmonary disease determines prognosis; it is worse than in the patients who do not have ILD. The prognosis and response to treatment are worse in patients with DM (Table 161.13).

TABLE 161.10: Clinical course of dermatomyositis/polymyositis related ILD

1. Acute fulminant disease with fever and respiratory failure
2. Slowly progressive disease lasting years
3. Asymptomatic disease with abnormal chest X-ray and abnormal functions

2. Usual interstitial pneumonitis
3. Bronchiolitis obliterans organizing pneumonia
4. Cellular interstitial pneumonia
5. Diffuse alveolar damage

TABLE 161.13: Factors suggesting good therapeutic response of DM-PM pulmonary disease

1. Young age
2. Polymyositis rather than dermatomyositis
3. Cryptogenic obliterative obstructive pneumonitis
4. High serum CK level at the time of onset of ILD
5. Alveolar infiltrate or ground glass attenuation
6. Little or no fibrosis on HRCT or lung biopsy

The diagnosis of ILD in DM and PM can be established by the clinical presentation, chest X-ray, high resolution CT scan and pulmonary function tests. The major radiographical finding is diffuse reticulonodular interstitial changes found predominantly in the lung bases (Fig. 161.14). Thin-section or high resolution chest CT is an excellent technique for characterizing nonspecific interstitial changes on chest X-ray. Typical patterns include ground glass opacification, basilar consolidation, septal thickening, honeycombing and

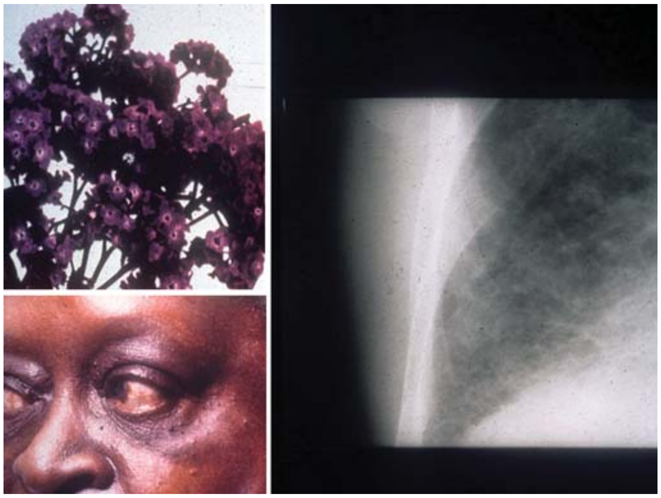

Fig. 161.14: A composite picture showing bluish purple hue of the face and fine nodular haziness of the lung in a patient with dermatomysitis

irregular linear opacities. The Jo-1 antigen, precipitating antibody to an acidic nuclear protein antigen is an important marker of the PM-DM associated ILD.[79,80]

Treatment of ILD in patients with myositis almost always requires glucocorticoids, regardless of whether pulmonary or muscle disease is the predominant feature of the patient's illness. No controlled trials of glucocorticoids have been undertaken; about 50% of myositis patients with ILD respond to corticosteroids.

Since ILD is a fatal disease, a second agent is added from the beginning of therapy in patients with DM or PM complicated by ILD. Options for this second agent in patients with mild ILD include azathioprine and methotrexate; azathioprine is preferred because of its favorable side effect profile. In patients with moderate to severe ILD cyclophosphamide is given. In patients with inexorable disease, rituximab and Intravenous Immune Globulin (IVIG) are the most commonly used treatment options.[81,82]

Respiratory Muscle Weakness

Respiratory muscle weakness occurs in 4 to 8% of patients with DM or PM. Typical inflammatory myopathic changes have been seen in the diaphragm, intercostal muscles and accessory muscles. Respiratory muscle weakness can cause mild dyspnea, linear or plate-like changes on chest X-ray, respiratory failure and hypercapnic coma. The patients with expiratory muscle strength less than 30% of normal and FVC less than 55% of predicted normal are prone for developing hypercapnia.

TABLE 161.14: Pulmonary manifestations of ankylosing spondylitis

1. Upper lobe fibrosis
2. Upper lobe cavities with fungus balls
3. Interstitial lung disease
4. Pleural effusion/thickening
5. Sleep apnea syndrome
6. Pneumothorax

Lung infection is common in DM and PM. Prophylaxis with trimmethoprim-sulfamethoxazole against *P. jirovecii* is given to the patients with DM or PM-ILD who are treated with high-dose glucocorticoids and immunosuppressive agents.

ANKYLOSING SPONDYLITIS

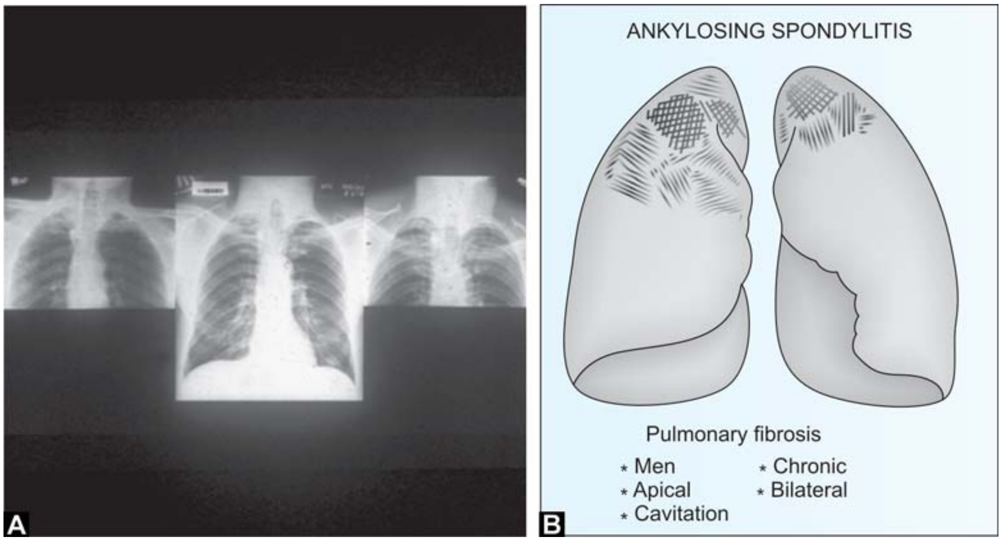
Ankylosing Spondylitis (AS) is a chronic progressive inflammatory rheumatic disease that affects primarily the sacroiliac joints and the axial skeleton. The disease is two to three times more common in men than in women, and is strongly associated with HLA-B27, a histocompatibility antigen I. A wide variety of pulmonary manifestations are seen in ankylosing spondylitis[83,84] (Table 161.14).

Upper Lobe Fibrosis

Upper lobe fibrosis is the most common extra-articular manifestation of AS. Occurring predominantly in men, the infiltrate may be unilateral, bilateral, acute or chronic, solid or cavitary. The cavities may become colonized with fungi or mycobacterial agents. In a study of 1,028 cases of AS seen in a tertiary referral centre over a 10-year period, 22 patients (2.1%) were found to have apical lung fibrosis on chest radiographs (Figs 161.15A and B). The HRCT imaging, however, reveals higher prevalence of apical fibrosis. The clinical significance of the HRCT abnormalities that are common in asymptomatic AS patients is uncertain[85-89] (Table 161.15).

TABLE 161.15: HRCT abnormalities in AS-related lung disease

1. Apical fibrosis
2. Thin-walled cavities
3. Fungus ball
4. Non-specific parenchymal abnormalities
5. Hilar/mediastinal adenopathy
6. Emphysema
7. Pleural changes



Figs 161.15A and B: A composite picture showing upper lobe lesions in a patient with ankylosing spondylitis

The pathogenesis of the apical fibrosis and other lung abnormalities seen in AS lesion is not known. Histological features include hyaline and elastic degeneration with interstitial fibrosis. Granulomas and vasculitis are absent. The lung function abnormality is restrictive in nature. Most of the patients are asymptomatic and treatment is not required. In symptomatic patients with active inflammation, non-steroidal anti-inflammatory agents have been used. The European League against Rheumatism has recommended the use of anti-TNF agents in AS patients with persistent activity, despite conventional treatment with non-steroidal drugs.[90-92]

Sleep Apnea Syndrome

The prevalence of sleep apnea syndrome is higher in AS patients then in general population. It has been suggested that AS predisposes to sleep apnea via different mechanisms that include restriction of the oropharyngeal airway due to cervical spine or temporomandibular arthritis, compression of medullary centers or by restrictive lung disease. Fatigue, a common symptom of AS, may be related to sleep apnea syndrome.[93]

Pneumothorax

A rare manifestation of pulmonary involvement in AS is due to rupture of fibrocystic foci. Due to the tendency of recurrence, prophylactic measures should be undertaken.[94]

Respiratory Muscle Weakness

Maximum inspiratory pressure, maximum expiratory pressure and maximum voluntary ventilation are reduced in AS. The respiratory muscle strength seems to correlate with diminished chest expansion.

MIXED CONNECTIVE TISSUE DISEASE (MCTD)

The pathogenesis and pathophysiology of MCTD are not well known. The clinical, radiological and physiological features of lung involvement in MCTD are similar to those observed in progressive systemic sclerosis in particular and other connective tissue diseases in general.[95,96]

Interstitial Lung Disease

The pathological features of ILD in MCTD are much like those seen in IPF, and include alveolarseptal infiltration by lymphocytes, plasma cells and type III collagen fibers. Corticosteroids and cytotoxic agents, such as chlorambucil and cyclophosphamide, are effective in acute inflammatory state.[97,98]

Pleural Effusion

Pleuritis occurs in about one-third of all the patients with MTCD. Occasionally, bilateral pleural inflammation is the initial event of MCTD; the fluid is usually exudative. Pleural thickening is uncommon.

TABLE 161.16: Principles of therapy in collagen vascular disease

1. Corticosteroids, cyclophosphamide, methotrexate and azathioprine and biological agents are the main drugs used
2. Rheumatoid arthritis-related ILD responds to corticosteroids and methotrexate
3. Corticosteroids are not useful in scleroderma-related lung disease; cyclophosphamide is the drug of choice
4. Acute lupus pneumonitis responds to corticosteroids
5. Collagen vascular disease-related BOOP/CP has good prognosis and responds to corticosteroids
6. Polymyositis-dermatomyositis related lung disease is fatal, corticosteroids and cyclophosphamide should be used

Pulmonary Hypertension

Progressive pulmonary hypertension is the most serious pulmonary complication of MCTD. It is often accompanied by severe systemic vasculitic lesions. In one study, out of all the patients studied, 67% had pulmonary hypertension. In these patients, elevated pulmonary vascular resistance was associated with impairment of diffusion capacity. Lung biopsy specimens reveal muscular hypertrophy of the small pulmonary arteries. Plexogenic angiopathy and intimal thickening of medium-sized arteries has been observed. Fatal pulmonary hypertension has been reported in MCTD patients.[99,100]

TREATMENT

Principle of therapy in collagen vascular diseases has been highlighted in Table 161.16.

CONCLUSION

Collagen vascular diseases form a heterogeneous group of autoimmune mediated inflammatory disorders. Pulmonary involvement is common. It is necessary to differentiate the primary lung disease related to the disease process from the super-imposed secondary infections and drug-induced changes. The treatment options are limited and include corticosteroids, immunosuppressive drugs and newer biological agents.

Pulmonary Manifestations of Systemic Diseases: An Approach

Ajmal Khan, SK Jindal

The lungs with their dual blood circulation and an open airway system exposed to the environment are liable to get involved in systemic diseases as well as in diseases of other organ systems. The spectrum of pulmonary manifestations due to systematic diseases are broad, accordingly, a major source of morbidity and mortality. This chapter is focused on important pulmonary manifestations of gastrointestinal and hepatic disorders.

ENDOCRINAL DISORDERS

Endocrine diseases can present with different respiratory symptoms. Respiratory problems may occur indirectly due to an increased risk of infection (as in diabetes) or due to upper airway obstruction secondary to goiter. Alterations in pulmonary function associated with disorders of the endocrine system can also occur due to the direct involvement of the respiratory system or its components.

Diabetes Mellitus

Diabetes is a systemic disease that produces structural and functional changes, particularly in the connective tissues, leading to end-organ damage in eyes, kidneys and nervous system. Microangiopathic processes and non-enzymatic glycosylation of tissue proteins at chronically high circulating glucose levels, together impair the collagen and elastin cross-linkage with reduction in the strength and the elasticity of connective tissue leading to functional derangement of end organs. Since the alveolar capillary network constitutes the largest microvascular organ in the body, it is highly susceptible to systemic microangiopathy. However, owing to a large physiological reserve of gas exchange, clinical manifestation and disability develop later in the lung than in the smaller microvasculature such as in the kidneys and the retina. In some cases, it may remain subtle and under recognized by both the endocrinologists and the chest physicians.

Diabetes can cause several clinical and functional respiratory complications (Table 162.1). Abnormal lung function can be detected in up to 73% of young asymptomatic type 1 diabetic patients.[1] Various cross-sectional studies have shown decreased Forced Vital Capacity (FVC), Forced Expiratory Volume in One Second (FEV_1) by 8-20% in both type 1 and type 2 diabetes mellitus consistent with modest restrictive defect without airway obstruction.[2-4] Similar observation of modest impairment is pulmonary function in a restrictive pattern has been observed in two recent systematic reviews of 74 studies involving more than 5000 patients

TABLE 162.1: Pulmonary complications of diabetes mellitus

Functional abnormalities
- ↓ Vital capacity
- ↓ Total lung capacity
- ↓ Diffusion capacity for carbon monoxide
- ↓ Inspiratory muscle strength
- ↓ Cough reflex

Sleep disordered breathing

Increase risk of infection
- Tuberculosis
- Fungal infections
- Legionella pneumonia

Aspiration pneumonia

However, longitudinal obser-vations over a 5- and 15-year follow-up period demonstrated that the rate of decline of FEV_1, and FVC is generally non-progressive in diabetic individuals in the long term, similar to that observed in non-diabetic subjects.[2,5] Similarly, reduction in total lung capacity and end expiratory lung volume of up to 30% below normal, which is inversely related to glycosylated hemoglobin levels, has been demonstrated in large cohorts of diabetes.[3,6,7]

Diabetic microangiopathy can also involve alveolar tissue and capillaries leading to reduction in alveolar gas transport, as manifested by reduced Diffusing Capacity of the Lung for Carbon Monoxide (DL_{CO}). Although a few studies have reported a normal lung diffusing capacity, majority of studies reported a reduced diffusing capacity among diabetic patients which is correlated with microangiopathy in other organs, duration of diabetes and microalbuminuria.[8-15] Based on available evidence, routine pulmonary function testing in diabetics is not warranted due to the small and clinically insignificant derangement in lung functions.

Subclinical autonomic dysfunction can occur within a year of diagnosis in type 2 diabetes and within two years in type 1 diabetes patients.[16] Reduced or absent cough reflex, diminished perception of inspiratory loading, sleep disordered breathing and aspiration are all associated with autonomic dysfunction in diabetic patients.[17-20] Clinically, there is depressed vagal tone manifested by blunted bronchodilator effect of anticholinergic agents and preservation of an intact end-organ response, supported by the findings of absent bronchoconstrictive response to cold-air provocation with normal or increased bronchial smooth muscle reactivity to direct stimuli with inhaled histamine.[21-23]

Diabetes mellitus with associated hyperglycemia is a risk factor for the development tuberculosis and is highlighted in several retrospective and prospective studies.[24-27] In the retrospective studies, the risk of acquiring tuberculosis in diabetes mellitus was as high as 4.8% compared to 0.8% risk in general population; type 1 diabetes mellitus was associated with 38 times more risk than in general population.[24] In countries with high incidence of tuberculosis, it is the most common complicating illness seen in diabetics.[25, 27] Surprisingly, the rate of infection with *Mycobacterium tuberculosis* is similar in both diabetics and matched controls as opposed to relative risk of 3.5 times higher in diabetics for development of pulmonary tuberculosis.[28] Routine screening for TB is recommended in a high prevalence country especially in children and adolescents with type I diabetes mellitus.[29]

Although clinical features, sputum positivity rate, response to anti-tubercular drugs are similar in diabetes mellitus and general population, radiological predilection for lower lung fields, tendency to cavitate and multilobar involvement are more frequently found in diabetics.[30, 31]

Thyroid Dysfunction

Thyroid hormones play a crucial role in lung development, surfactant synthesis and lung defenses. Consequently, both hyperthyroidism and hypothyroidism may alter the functions of respiratory system and result in several different clinical complications (Table 162.2). Both the excess and the deficiency of thyroid hormones can contribute to dyspnea and exercise limitation through the common mechanism of congestive heart failure or myopathy leading to respiratory muscle weakness and respiratory failure. Pleural effusion due to hypothyroidism *per se* or secondary to pericardial involvement may cause respiratory symptoms which resolve with treatment of hypothyroidism.

Obstructive manifestations, such as dyspnea, stridor, wheezing, hoarseness or cough produced by goiter, can occur by direct compression of the extrathoracic or intrathoracic trachea. Compression or irritation of the recurrent laryngeal nerves may result in airway obstruction due to vocal cord paralysis. Both the conditions remain obscured by other common causes of airway obstruction, unless specifically searched. The presence of dynamic obstruction can be demonstrated by the characteristic dampening of both the inspiratory and the expiratory curves on flow volume loop during lung function testing. One of the most consistent finding in hypothyroidism is its influence on the central ventilatory control. Both hypoxic ventilatory drive and hypercapnic ventilatory response are depressed in hypothyroidism. The blunting is more marked in

TABLE 162.2: Pulmonary complications of thyroid dysfunction

Functional abnormalities
- Characteristic dampening of inspiratory and expiratory flow volume loop in goiter
- ↓ Inspiratory muscle strength due to myopathy
- Blunted ventilatory response to hypoxia
- Blunted hypercapnic ventilatory response

Sleep apnea
- Central
- Obstructive

Pleural effusion
- Hypothyroid pleural effusion
- Hypothyroid associated effusion due to pericardial involvement

myxedema which can effectively be improved with thyroid hormone replacement.[32-34] Blunted ventilatory response is an important cause of increasing failure; approximately 3% of the mechanically ventilated patients who have weaning failure are subsequently detected to have hypothyroidism.[35]

In hypothyroidism, respiratory disturbances due to sleep apnea are observed in up to 50-100% of patients besides, the fact that the prevalence of hypothyroidism in sleep apnea is very low.[36,37] Both central apnea due to blunted ventilatory response to hypoxia and obstructive apnea secondary to deposition of mucopolysaccharides in the oropharynx and tongue leading to narrowing of upper airway during sleep can occur in hypothyroidism. Although hormone replacement leads to normalization of sleep apnea, a few patients may require continuous positive airway pressure support on the long-term basis.[38,39]

Acromegaly

Acromegaly is characterized by excessive bony growth, soft tissue hypertrophy and facial coarsening consequent to excessive release of growth hormone, most commonly from a pituitary adenoma. In patients with acromegaly, macroglossia, nasal polyps, oropharyngeal airway narrowing and vocal cord dysfunction are common features which predispose to respiratory disturbances and sleep apnea. Inspiratory pharyngeal collapse during sleep due to hypertrophy of parapharyngeal and retropharyngeal soft tissue and an enlarged tongue are some of the important causes of obstructive sleep apnea in acromegaly.[37] Neck circumference of greater than 41 cm and the circumference of the index finger of above 8.5 cm were found as good predictors of development of sleep apnea in acromegaly. Other respiratory problems which are commonly seen in acromegaly are extrathoracic airway obstruction, difficult intubation and vocal cord dysfunction.

GASTROINTESTINAL DISEASES

Due to close anatomical proximity and continuity of abdominal viscera to the thorax, any intra-abdominal pathology can secondarily involve the lungs, but more commonly few specific diseases have simultaneous and pronounced pulmonary manifestations.

Gastroesophageal Reflux Disease

TABLE 162.3: Pulmonary disorders associated with gastroesophageal reflux

- Chronic cough
- Bronchial asthma
- Aspiration pneumonia, lung abscess, bronchiectasis
- Vocal cord dysfunction
- Chronic bronchitis
- Idiopathic pulmonary fibrosis

Gastroesophageal Reflux Disease (GERD) may trigger, exacerbate or possibly cause many pulmonary diseases (Table 162.3). Despite extensive studies addressing the pathophysiological link between respiratory symptoms and reflux disease, the true relationship in the population remains uncertain. Patients with chronic cough and asthma have a high prevalence of GERD. Therefore, many guidelines recommend consideration of GERD in the routine work-up of patients with wheezing and chronic cough, whether the association is causal or casual is yet to be determined.

There is clear documentation of higher prevalence of GERD in asthma and chronic cough than in the general population with approximately 75-80% of asthmatics showing reflux symptoms.[40, 41] In addition GERD has been postulated as a potential trigger for asthma.[42] Mechanisms by which GERD leads to respiratory symptoms are:

- Microaspiration of frequent small volume aspirate from the proximal esophagus leads to laryngeal and/or tracheobronchial mucosal reaction and symptoms of hoarseness, cough or wheezing.
- Reflux of acid from the lower esophagus may lead to reflex activation of vagus nerve and bronchoconstriction. Common embryonic origin of the esophagus and lung, together with common vagal innervations of these organs, further supports this hypothesis.
- Gross aspiration of gastric contents may result due to the presence of an anatomical or physiological abnormality in the lower esophageal sphincter. These patients commonly present with aspiration pneumonia, lung abscess and bronchiectasis.

Furthermore, physiological alterations associated with asthma or its treatment may themselves promote gastroesophageal reflux. Transient lower esophageal sphincter relaxation and negative pressure generated during episode of coughing or bronchoconstriction and flattening of diaphragm secondary to hyperinflation are commonly seen in asthmatics and are associated with change in the pressure gradient between the thorax and the abdomen. Similarly, beta agonists and theophylline dilate the smooth muscle throughout the body including at the lower esophagus disrupting the gastroesophageal physiological barrier. Both of these factors may lead to GERD in asthma.

The presence of gastroesophageal reflux as an important trigger in patients with asthma has been recently disputed. It was shown in a large double-blind trial that silent GERD was not a likely cause of poorly controlled asthma.[43] Only a specific subgroup of patients with respiratory symptoms may respond to therapy for GERD, which should include a combination of antireflux measures such as the weight reduction, avoidance of meals before bedtime, eating low fat diet and acid suppressive therapy.

Acute Pancreatitis

Pulmonary complications are the most frequent and potentially the most serious systemic complications of acute pancreatitis. The spectrum of pulmonary sequelae of acute pancreatitis range from subclinical arterial hypoxemia to frank acute respiratory distress syndrome (ARDS)[44,45] (Table 162.4). When present, these sequelae are associated with significant mortality. Respiratory dysfunction precedes the occurrence of heart, liver and renal failure and is responsible for early deaths in severe acute pancreatitis.[46]

Arterial Hypoxemia and Respiratory Failure

During early stages of acute pancreatitis, subclinical arterial hypoxemia is a frequent occurrence. Several studies have demonstrated arterial hypoxemia ($PaO_2 < 80$ mm Hg) in up to 55 to 65% of patients during the first 48 hours without any obvious clinical or radiological abnormality, they are associated with significantly higher mortality.[47-50] The mortality rises to 14% at PaO_2 less than 60 mm Hg, from 6% at PaO_2 less than 70 mm Hg.[44] Similarly, in another study, mortality of 60% was observed in 22% patients of acute pancreatitis with severe respiratory insufficiency.[51] These studies clearly suggest that respiratory insufficiency, early in acute pancreatitis, is a predictor of poor outcome.

Hypoxemia in these patients is predominantly caused by ventilation perfusion mismatch resulting in right to left intrapulmonary shunting of approximately 30% of the cardiac output.[52] Changes in pulmonary vascular permeability and reduction in oxygen affinity of hemoglobin related to increase in circulating fatty acids are the other few mechanisms proposed for hypoxemia in acute pancreatitis.[52,53] Due to the subclinical nature and normal chest radiograph, a high index of suspicion and close monitoring are required to detect hypoxemia, especially during the first 72 hours. Supplemental oxygen is indicated to keep the arterial PaO_2 more than 70 mm Hg.

TABLE 162.4: Pulmonary complications of acute pancreatitis

- Pleural effusion
- Atelectasis
- Mediastinal abscess
- Pneumonitis
- Pulmonary infarction
- Acute respiratory distress syndrome

Acute Respiratory Distress Syndrome

The most serious pulmonary complication of acute pancreatitis is ARDS, seen in approximately 15–20% patients with an associated mortality of 50 to 75%.[48,54-56] Usually, persistent and refractory hypoxemia evolves to overt ARDS in 2–7 days, but may have rapid onset and course. Rapid appearance and progression to multilobar infiltrates is classically noted on chest radiography. Although the exact mechanism of lung injury is poorly understood, pancreatic enzymes and inflammatory mediators play a key role in its pathophysiology. Phospholipase A_2 binds to pulmonary capillaries and has the potential to induce the enzymatic degradation of phospholipid component of surfactant leading to increased vascular permeability and alveolar collapse.[57, 58] Free fatty acids released from triglycerides by pul-monary lipases lead to capillary and alveolar wall damage and alveolar edema.[59]

Standard supportive treatment for acute pancreatitis consists of nutrition maintenance, hemodynamic management and suppression of secretory function of pancreas. Management of lung injury with lung protective ventilation is similar to that for other forms of ARDS with an aim to maintain oxygen delivery to all organ systems. Specific treatments, such as protease inhibitors and antioxidants, targeted to pancreatic injury have failed to decrease the severity of the disease.

Pleural Effusion

Pleural effusion is a frequent complication of both acute and chronic pancreatitis with an associated mortality of 20 to 30%.[60] When present, the effusions are usually small, left sided, occasionally bloody and are indicators of severe disease.[61,62] Effusion is usually exudative, serosanguineous in appearance with high amylase, protein and lactate dehydrogenase. The main mechanisms proposed for effusion in acute pancreatitis are:

- *Increased permeability of lymphatics:* Pancreatic enzyme causes fluid leak that diffuses from peritoneal side to the pleural space through pores in the diaphragm.

- *Impaired lymphatic drainage:* High enzymatic content and exudate in the pleural fluid causes obstruction of the lymphatics.
- *Increased permeability of diaphragmatic capillaries:* Caused by inflammatory process in the adjacent pancreas.
- *Pancreaticopleural fistulae:* Secondary to leak and disruption of pancreatic duct.

Pancreatitis related effusions are usually self-limited and resolve spontaneously without any therapeutic intervention when the pancreatic inflammation subsides. Persistence of effusion indicates the occurrence of complications, like pancreatic abscess or pseudocyst formation. Symptomatic effusions may be drained with thoracentesis or tube thoracotomy, while chronic effusions often require drainage of the pseudocyst or of abscess, or excision of the fistulous tract.

HEPATIC DISORDERS

Hepatic Hydrothorax

In the absence of a coexisting cardiopulmonary disease, development of pleural effusion in cirrhosis of the liver with portal hypertension is termed as hepatic hydrothorax. It can complicate approximately 5-10% of cirrhotic liver irrespective of the underlying etiology.[63] Due to the pressure gradient between the abdominal and the pleural cavities, the fluid from the abdominal cavity moves to the pleural space via the small defects in the diaphragm. Additionally, intravascular volume expansion secondary to sodium retention and hypoalbuminemia contributes to the development of hydrothorax. The effusion is essentially a transudate with its origin in the peritoneal cavity. An exudative character of the fluid should raise the suspicion of tuberculous effusion or of secondary bacterial infection.

Sometimes, ultrasonography or nuclear scan is required to establish the presence of ascites.[64] In a majority, the effusion is small or of moderate size predominantly on the right side, but left sided, bilateral and massive effusion is not infrequent. In an appropriate clinical setting, similarity between the pleural and the peritoneal fluid establishes the diagnosis. Liver transplantation is the definitive treatment of choice. Transjugular intrahepatic portosystemic shunt, thoracoscopic repair of the diaphragmatic defect and pleurodesis are alternative options when definitive therapy is not feasible.

Hepatopulmonary Syndrome (HPS)

The association of liver disease with widespread intrapulmonary vasodilation and impaired arterial oxygenation is known as hepatopulmonary syndrome.[65,66] The coexistence of decreased lung compliance and reduced diaphragmatic motility due to massive ascites characteristically leads to hyperventilation and corresponding hypocapnia because of which increased alveolar-arterial oxygen gradient becomes the most sensitive method to detect pulmonary gas exchange disturbances.

Pathophysiology

The characteristic histopathological pulmonary vascular changes in HPS consist of dilated vessels at the precapillary, capillary and postcapillary levels leading to intrapulmonary shunting of mixed venous blood into the pulmonary vein.[67]

The precise pathophysiological mechanism underlying HPS remains uncertain. Excessive production or altered clearance of vasodilator molecule such as nitric oxide is considered as one of the mechanism for hyperkinetic circulation in HPS.[68, 69] Several mechanisms have been proposed for the gas exchange abnormalities seen in HPS:

- *Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch:* It occurs in mild to moderate HPS due to the areas of preserved ventilation but profoundly increased perfusion. Impaired hypoxic pulmonary vasoconstriction seen in advanced liver disease contributes to this $\dot{V}/\dot{Q}$ mismatch.[70,71]
- *Increased intrapulmonary shunting:* It is the primary abnormality in severe HPS.
- *Diffusion-perfusion defects:* Oxygen from the alveoli fails to diffuse to oxygenate the hemoglobin.[72,73] Additionally, coexistence of hyperdynamic circulation leads to shorter transit time for red blood cells that would further aggravate diffusion induced gas exchange disturbance.

Clinical Features

Most patients have prominent clinical and functional features of advanced liver disease such as jaundice, ascites, palmar erythema, liver and splenic enlargements. Extensive cutaneous spider nevi which are seen more commonly in patients with HPS are considered as a cutaneous marker of both systemic and intrapulmonary vasodilatation.[70] Specific pulmonary features consist of dyspnea, platypnea, orthodeoxia, cyanosis and digital

TABLE 162.5: Diagnostic criteria for hepatopulmonary syndrome[66]

Essential features:
- Presence of chronic hepatic disease
- Normal or near normal chest radiography (with nodular basal shadowing)
- Pulmonary gas exchange abnormalities - ↑ (A - a)PaO_2 of ≥15 mm Hg with or without concomitant arterial hypoxemia (arterial PaO_2 <80 mm Hg)
- Positive contrast enhanced-echocardiogram or abnormal intravenous radiolabeled perfusion lung scan or both

Additional features:
- ↓ DLCO
- Dyspnea with or without platypnea and orthodeoxia
- Hyperkinetic circulatory state with normal or low pulmonary artery pressure

clubbing. Increased dyspnea in the upright position (i.e. platypnea) and orthodeoxia (i.e. decrease of PaO_2 ≥5% or >4 mm Hg from the supine to the upright position) are the characteristic, but not pathognomonic features of HPS.[74,75]

Diagnosis

In patient with chronic liver disease, presence of platypnea, orthodeoxia and clubbing strongly suggest a diagnosis of HPS (Table 162.5). Hyperkinetic circulation, systemic hypotension, low or normal pulmonary artery pressure with normal or low pulmonary vascular resistance are the characteristic hemodynamic features.

Two dimensional contrast-enhanced echocardiography provides a sensitive, noninvasive and qualitative screening tool to identify intrapulmonary shunting, now considered as the gold standard.[76,77] Demonstration of microbubbles (60–90 µm in diameter) of air in the left heart chambers within 3–6 beats of their visualization in the right heart chambers is almost diagnostic of this condition. In normal individuals, intravenously injected microbubbles are trapped in the pulmonary circulation and removed. Simultaneous appearance of microbubbles in the left heart chambers differentiates intracardiac from intrapulmonary shunts. The only limitation of this technique is its inability to differentiate between different forms of intrapulmonary vascular deformities.

Alternative demonstration of technetium-99m labeled macroaggregated albumin activity over extrapulmonary organs suggests right to left shunting, but the method is limited by its inability to differentiate between intracardiac and intrapulmonary shunting. In healthy individuals, only 3–6% of albumin macroaggregates pass through the pulmonary vasculature to organs like the brain, the kidney and the liver, but, in the presence of pulmonary vasodilatation, the shunt ratio is 10–71%.[78,79]

Treatment

Orthotopic liver transplantation has been shown as an effective measure for complete resolution of HPS in approximately 80% of the patients.[80-82] Alternatively, medical management with agents like bismesylate almitrine, long-term oxygen therapy and propranolol has been tried to reduce the shunt but the results are disappointing. A few centers have also tried palliative measures like embolization of pulmonary fistulas, portal decompression with transjugular intrahepatic portosystemic shunting.[83,84]

Portopulmonary Hypertension

Portopulmonary Hypertension (PoPH) is defined hemodynamically as an elevated mean Pulmonary Arterial Pressure (mPAP) >25 mm Hg, an increased pulmonary vascular resistance (PVR) greater than 240 dynes/sec/cm^5 and a normal pulmonary artery occlusion pressure (<15 mm Hg) in a patient who has portal hypertension with or without cirrhosis. The condition is both pathophysiologically and clinically different from HPS (Table 162.6). The prevalence of PoPH is around 0.61–2%, recent studies from orthotopic liver transplant centers show higher prevalence of 4 to 5%.

TABLE 162.6: Differentiation between hepatopulmonary syndrome and portopulmonary hypertension

	Hepatopulmonary syndrome	*Portopulmonary hypertension*
Causes	Liver disease with portal hypertension	Liver disease with portal hypertension
Pathophysiology	Pulmonary vasodilation	Pulmonary vasoconstriction
Symptoms	Platypnea, Orthodeoxia	Dyspnea, Edema
PaO_2	Hypoxemia, Orthodeoxia	Hypoxemia at late stages
Chest X-ray	Usually normal	Signs of pulmonary hypertension
Contrast ECHO	Late (>3–6 cardiac cycles) appearance of microbubbles in left atrium	Usually negative
Cardiac output	Increased	Normal or decreased
Pulmonary vascular resistance	Decreased	Increased
Shunt	>10%	Nil

Histopathologically, PoPH is characterized by medial hypertrophy, plexogenic and thrombotic pulmonary arteriopathy, indistinguishable from primary pulmonary hypertension.[85] The combination of vasoconstriction, vascular proliferative response and in situ microthrombosis underlie the increase in PVR seen in patients with PoPH. Portosystemic shunting of vasoactive agents like thromboxanes, serotonin and bradykinin due to altered hepatic metabolism is postulated as a possible mechanism for pulmonary arterial vasoconstriction.[86] Endothelial damage with vascular remodeling caused by excessive pulmonary blood flow and microvascular thrombosis may also contribute.

The clinical picture in PoPH is indistinguishable from that of primary pulmonary hypertension and appears late in the evolution of the disease. Predominantly, patients have exertional dyspnea. As the severity increases, peripheral edema, fatigue, abdominal bloating, palpitation and syncope may appear.

Prominent pulmonary artery and cardiomegaly are seen on chest radiography. Transthoracic Doppler echocardiogram is the screening procedure of choice in patients with liver disease and unexplained dyspnea. Features suggestive of PoPH on echocardiography include the elevation of right ventricular systolic pressure (calculated from the peak tricuspid regurgitant velocity using modified Bernoulli equation and an estimate of right atrial pressure), shortened pulmonary acceleration time, paradoxical septum motion, and right-ventricular hypertrophy and dilatation.[87] Using right ventricular systolic pressure cutoff of 40 mm Hg, Doppler echocardiography has a sensitivity and specificity of 80% and 96% respectively, but it cannot differentiate between elevated PVR and hyperdynamic circulation (low or normal PVR) as a cause of pulmonary hypertension.[88] Confirmation of the diagnosis of PoPH requires right heart catheterization which permits measurements of pulmonary artery pressure, PVR, pulmonary artery wedge pressure and of cardiac output.

Treatment aimed at lowering pulmonary artery pressure and resistance is indicated in all symptomatic patients. Diuretic administration is required for the associated cor pulmonale and volume overload. Anticoagulation is often contraindicated due to the associated hemorrhagic diathesis related to liver disease and its complications. Supplemental oxygen to maintain saturation above 90% is beneficial for all patients. Drugs with vasodilating and vasomodulating effects can be given but there are no randomized controlled trials specific to this population. Use of these drugs should be individualized depending upon the severity of the disease and prospects for liver transplantation.

Orthotropic liver transplantation can be beneficial in a highly selected subset of patients but the resolution of pulmonary hypertension after transplantation is not universal. Both intraoperative and immediate postoperative complications of liver transplantation are also high because of the associated comorbidities and deranged hemodynamics.

RENAL DISEASES

Chronic renal failure usually affects the lung indirectly by affecting the other organ systems of body such as through raised pulmonary venous pressure and anemia. A transient respiratory gas exchange abnormality following hemodialysis is also a frequent occurrence. The common renal complications are discussed under Table 162.7.

TABLE 162.7: Pulmonary complications of renal failure

Pulmonary edema
Pleural diseases
- Pleural rub
- Pleural effusion
- Fibrosing uremic pleuritis/Fibrothorax

Pulmonary calcifications
Sleep apneas
Hemodialysis-induced gas exchanges abnormalities

Pulmonary Edema

Subclinical or overt pulmonary edema is common in renal failure due to a number of different mechanisms:

- Fluid overload
- Hypoproteinemia with reduced plasma colloid pressure
- Depressed myocardial function
- Increased microvascular permeability

The characteristic distribution of edema in the more central part of the lungs is explained by the diversion of flow through the shortest arterial pathway. Hypertension, diabetes mellitus, anemia and ischemic heart disease commonly seen in end-stage renal disease may also adversely affect the heart.

Pleural Effusion

Pleural effusion is seen in approximately 3% of patients of renal failure.[89] The exact mechanism of pleural disease is not understood, it is probably similar to that of pericarditis seen in uremia. Almost half of the patients with pleural effusion are symptomatic with fever, chest pain, cough or dyspnea; the degree and severity of uremia have no correlation with the occurrence of effusion.[89] Both transudative or exudative effusion can occur; most commonly it is an exudate which is frequently serosanguineous or frankly hemorrhagic.[90,91] Lymphocytes are the predominant cells, pleural biopsy characteristically reveals chronic fibrinous pleuritis. Transudative effusions are seen in the fluid overload states and in congestive heart failure. Confident diagnosis of uremic pleuritis requires exclusion of other common causes of effusion like pleural infection especially tuberculosis, malignancy and pulmonary embolism.[92]

Effusion routinely disappears with dialysis in 4–6 weeks in most cases. In 25% of patients it may persist, progress or recur. In a small number of patients, progressive pleural thickening may lead to ventilatory defects and require surgical decortication.[93,94]

Hemodialysis-induced Pulmonary Gas Exchange Abnormalities

Arterial hypoxemia during dialysis is a common occurrence. A fall in arterial PaO_2 of 10–15 mm Hg is observed within few minutes of dialysis, reaches a plateau after 45–60 minutes and persists for the duration of dialysis.[95,96] Hypoxemia may occur due to several different mechanisms:

- Shift in oxyhemoglobin dissociation curve due to procedure related rise in pH
- Alkalosis-induced depression of central ventilatory drive
- Impairment of oxygen diffusion
- Ventilation-perfusion mismatching due to pulmonary leukostasis
- Loss of carbon dioxide via dialysate-induced hypoventilation

Hypoxemia during hemodialysis is now considered as a predictable effect of loss of carbon dioxide (CO_2) into the dialysis fluid. Removal of CO_2 into the dialysis fluid during hemodialysis leads to decrease in minute ventilation.[96,97] The diffusion of CO_2 into the dialysis fluid is substantially more with acetate buffer than with bicarbonate buffer.[98]

Due to the large cardiopulmonary reserve, the reduction in arterial PaO_2 has no significant effect in patients with normal cardiopulmonary function. In patients with compromised function, supplemental oxygen during hemodialysis should be given. Composition of dialysis membrane and the dialysate buffer should also be appropriately changed.

Vasculitides and Alveolar Hemorrhage Syndrome

The involvement of both lungs and kidneys in systemic vasculitides and granulomatoses commonly manifests with hemoptysis and renal failure.[99-101] Such a syndromic presentation may occasionally pose problems of differential diagnosis from primary renal disorders with pulmonary features.

OTHER SYSTEMIC DISEASES

Pulmonary manifestations are also common with rheumatological, and connective tissue disorders as well as with hematological and lymphatic diseases, either with primary or secondary involvement of the lungs. Similarly, diseases of brain, nerves, muscles and bones may also present with pulmonary complications. Readers are advised to refer to different chapters for their details.

Pulmonary Manifestations in Cardiovascular and Neuromuscular Diseases

Ajmal Khan, SK Jindal

CARDIOVASCULAR DISEASES

Embryological and anatomical relationship entails the heart and the lung in the thoracic cavity to complement the action of each other. Any deviation of this complementary action of pressure and volume or the gas exchange will have consequences on the others. Increase in pressure or volume in the pulmonary vasculature, as a consequence of ischemic, hypertensive or intrinsic left heart dysfunction induces abnormalities in the pulmonary volume and leads to disturbances in the gaseous exchange. Similarly, decreased pressure downstream curtails the force and endurance of the respiratory muscles, disposing them to mechanical disadvantage and ventilatory defects. On the other hand, an intrinsic defect in the parenchyma, airways or the vascular bed of the lungs produces right heart dysfunction that ultimately leads to altered geometry of the interventricular septum and compromised left heart function.

Cyclic physiological changes in the intracardiac hemodynamics induced by normal respiration is related to the variation in intrathoracic pressure, venous return, intrapericardial pressure and the interdependence of the cardiac chamber. Inspiration decreases intrathoracic and intrapericardial pressures leading to augmented filling and stroke volume of the right ventricle and a compensatory decrease in left ventricular stroke volume due to limited pericardial space. During expiration, these pressures increase and reciprocal changes ensues in two ventricles.

Heart Failure

Under normal condition, there is linear increase in the blood flow from apex to the base of the lung. Left heart failure and consequent increased left atrial pressure, as a result of various cardiac and extracardiac abnormalities causes shift of linear flow of blood to more uniformly distributed flow.[1] Modest increase in flow or pressures are accommodated and redistributed within the pulmonary venous circulation by capillary distension and recruitment without overt pulmonary edema. Additional safety mechanism that prevents edema formation is low permeability and active transport of alveolar epithelial cells, resorption into blood vessels and lymphatics and mediastinal and pleural drainage. A higher pulmonary filling, venous and capillary pressure promotes vascular distension and perivascular, peribronchiolar, interstitial and alveolar edema, leading to symptom complex of dyspnea, wheezing and exercise intolerance. This is shown in Table 163.1.[2-7]

Ventilatory Abnormalities

Alterations in the mechanical and gas-exchanging properties of the lungs, produced by left-sided heart failure of any cause are largely influenced by the water content of the lung. In general, Total Lung Capacity (TLC) and Functional Residual Capacities (FRC) are reduced,

TABLE 163.1: Mechanisms of dyspnea and exercise limitation in heart failure

- Decreased lung compliance[2]
- Bronchial hyper-responsiveness[3,4]
- Ventilation perfusion mismatch[5]
- Stimulation of lung stretch receptors[6]
- Respiratory muscle weakness[7]

whereas the residual volume may be normal or slightly increased.[8,9] The reduction in TLC is proportional to the severity of the heart disease. Influence of heart failure on resting dynamic pulmonary functions ranging from essentially normal values to primarily restrictive or obstructive defects to combined obstructive and restrictive defects with or without diffusion abnormalities are observed in various studies.[10-18] However, the majority of the studies are confounded by the changes due to normal aging, obesity and smoking. When changes in baseline pulmonary function influenced by stable chronic heart failure independent of these confounding factors were studied, only mild restrictive or normal values were observed.[8] Variable degrees of obstructive defects alone are more prevalent during periods of decompensation that improves with diuresis predominantly due to reduction in extravascular lung water and pulmonary and bronchial blood flow.[18-20] In stable patients, obstructive defects are predominantly related to adequacy of treatment, normal aging and smoking habits.[20]

These ventilatory abnormalities can be improved by the correction of the cardiac abnormalities, either through optimization of medical treatment or heart transplantation. Heart transplantation improves pulmonary function by 3 months and normal lung volumes and flows by one year following the surgery.[21,22]

The exact cause of restrictive defects in chronic heart failure remains elusive. Reduced lung compliance owing to cardiac size, augmented by increased interstitial fluid accumulation and general muscle weakness and wasting, likely accounts for the restrictive changes seen in heart failure. Additionally, parenchymal changes induced by increased levels of circulating cytokines, like tumor necrosis factor-α or pulmonary vascular remodeling due to chronic high left atrial pressures leads to altered lung compliance and consequent restrictive changes in the lung mechanics.

Diffusion Abnormalities

In heart failure, pulmonary diffusion impairment occur secondary to reduction in global perfusion of the lungs and a reduction in the conductance of the alveolar-capillary membrane.[15,18] Structural changes of the alveolar capillary membrane develop as the disease progresses, which leads to an impaired diffusion capacity. Decreased membrane conductance represents thickening of the alveolar-capillary barrier from the accumulation of fluid or fibrosis indirectly supported by the data from chronic heart failure patients, demonstrating reduced pulmonary microvascular permeability.[23] In the last decade, it has become increasingly evident that lung diffusion abnormalities not only strongly correlate with exercise performance and Congestive Heart Failure (CHF) severity, [24-26] but most importantly, with CHF prognosis as well.[27] In contrast to the ventilatory abnormalities, diffusion defects may not be fully reversible.[21,22,28]

Sleep Abnormalities

Another important pulmonary manifestation of heart failure is high prevalence of breathing abnormalities during sleep. Depending on the severity of heart failure, approximately 37 to 75% of patients will have Central Sleep Apnea (CSA) with periodic breathing or Cheyne-Stokes Respiration (CSR) and additional 10 to 25% of patients will have Obstructive Sleep Apnea (OSA).[29-31] The overlapping symptoms of heart failure and sleep apnea contributes to the underdiagnosis of sleep related breathing disorders in heart failure. However, presence of hypocapnia, atrial fibrillation, ventricular tachycardia, a low left ventricular ejection fraction, a high New York Heart Class (III and IV) and excess premature ventricular beats and couplets are clinical clues for the presence of sleep apnea in patients with heart failure. Ventilatory instability due to increased circulation time and increased loop gain in the metabolic control of ventilation is largely responsible for CSA, while predominantly upper airway collapse during sleep leads to OSA in heart failure.[32-34] Due to presence of CSA-CSR, CHF patients confers a worse prognosis, therapy with continuous positive pressure ventilation may ameliorate CSR-CSA and overall outcome by improving cardiac functions.

Neuromuscular Diseases

Pathological processes of the neuromuscular system can interfere with the function of the central nervous system, spinal cord, peripheral nerves, neuromuscular junction and muscles to produce respiratory manifestations. These disorders affect respiratory function, by weakening, singly or in combination, the muscles of inspiration particularly the diaphragm, muscles of expiration impairing cough and bulbar functions disrupting cough swallowing and speech. Consequently, aspiration associated with dysphonia is a common complication of neuromuscular disease.[35-37] Common final abnormality in these disorders is primarily ventilatory failure.

Assessment of Respiratory Muscle Function

Gas Exchange

Alveolar hypoventilation with a normal or elevated pH and a reduced arterial carbon dioxide (pCO_2), due to increased ventilatory drive is the initial manifestation of mild to moderate respiratory muscle weakness.[38] As the disease advances, further progression of muscle weakness leads to carbon dioxide retention. Other factors including altered control of breathing, compounded by blunted hypercapnic and hypoxic ventilatory drive, atelectasis and abnormal chest wall compliance may contribute for chronic hypercapnia seen in these patients.[9] Unless concomitant parenchymal or alveolar abnormality is present, arterial tension of oxygen (pO_2) and the alveolar-arterial oxygen tension gradient pO_2 (A–A) are normal.

Pulmonary Function Tests

Integrated function of respiratory muscle, nerves, airways and lung parenchyma can be assessed noninvasively by measuring TLC, Vital Capacity (VC) and Maximum Voluntary Ventilation (MVV). Alteration in the respiratory muscle and nerve limits the ability to lower intrathoracic pressure and reduces the ability to generate a full inspiration leading to restrictive defects. Furthermore, rapid and shallow breathing pattern due to neuromuscular weakness leads to increased dead space to tidal volume ratio that compromises their ventilatory function. [39] Characteristically, TLC and VC are reduced with normal or decreased FRC and when expiratory muscles are also severely involved Residual Volume (RV) is increased. [40-44] MVV is usually reduced similar or more than the VC. Due to sigmoid shape of the pressure volume relationship of the respiratory system, severe impairment of respiratory muscle strength (more than 50%) is required, before significant reduction in lung volumes is appreciated.[40] In contrast to the normal 10% drop in VC, when changing from upright to the supine position, VC may be reduced by more than 30% in the supine position in patients with bilateral diaphragmatic palsy. This positional variation is more sensitive indicator of respiratory muscle weakness than upright measurement of TLC and VC alone, however there is potential for false positive results in individuals without diaphragmatic palsy.[45]

In neuromuscular disorders reduction in FVC is proportional to the reduction in FEV_1, so that the ratio is preserved, unless concomitant obstructive processes are also present. This preserved ratio is largely because of above normal lung recoil and patent airways.

Respiratory Muscle Strength Assessment

Respiratory muscle weakness is the hallmark of neuromuscular disease that can be assessed by maximal static Inspiratory and Expiratory Pressures (PI max and PE max). PI max is measured at the airway opening during a maximal, static inspiratory effort (Muller maneuver) initiated at either FRC or RV, similarly PE max are measured at the airway opening during a maximal static expiratory effort (Valsalva maneuver). Generalized neuromuscular weakness reduces both PI max and PE max, however, these tests are totally dependent on effort and reproducibility of maximal pressures does not verify that maximal effort has been made.[46] Consequently, other factors like submaximal efforts or air leaks around the mouthpiece must be considered when low values are encountered. Alternatively, to reduce the variability, pressures during maximal sniff maneuvers measured at nose, esophagus or across the diaphragm can be performed. Maximal sniff maneuver is a more reliable means of assessing respiratory strength than the Muller maneuver in patients with inspiratory muscle weakness.[47-49]

Diaphragmatic Paralysis

The diaphragm is the most important muscle of ventilation, supplied by the phrenic nerve (C_3–C_5). It consists of noncontractile central tendon and contracting muscle fibers attached to the inner surface of the lower six ribs, costal cartilage anteriorly and to the upper three lumbar vertebral bodies posteriorly. In the supine breathing, the diaphragm alone is responsible for most of the inspiratory effort. Diaphragmatic paralysis may involve one leaflet (unilateral) or the whole diaphragm (bilateral). Causes of unilateral or bilateral diaphragmatic paralysis are more or less similar with different prevalence, as shown in Table 163.2.

TABLE 163.2: Etiologies of diaphragmatic paralysis

Neurological disorders	*Myopathic disorders*
Multiple sclerosis	Limb-girdle muscular dystrophy
Amyotrophic lateral sclerosis	Acid maltase deficiency
Spinal cord transection	Hypothyroidism or hyperthyroidism
Guillain-Barré syndrome	Systemic lupus erythematosus
Poliomyelitis	Mixed connective-tissue disease
Chronic inflammatory demyelinating polyneuropathy	Amyloidosis
Phrenic nerve lesions • Blunt trauma • Cardiac surgery	Malnutrition

TABLE 163.3: Difference between unilateral and bilateral

	Unilateral paralysis	*Bilateral paralysis*
Dyspnea	Absent or only on exertion	Always present
Orthopnea	Occasional	Unable to lie supine
Hypoxemia	Rare	Common
Hypercarbia	Rare	Common
FVC	Normal	Drop of > 30% from upright to supine
Chest X-ray	Eventeration of diaphragm	Bilateral small lungs due to atelectasis
Fluoroscopy	Sniff test positive	Absence of caudal displacement

Clinical Features

The degree of symptoms of diaphragmatic paralysis is variable, depending upon the underlying lesion (a uni or bilateral paralysis), concurrent lung or heart disorders and the degree of obesity as demonstrated in Table 163.3.[50,51] In unilateral disease, only shortness of breath upon undertaking of strenuous physical exertion or totally absence of symptoms may be present. Occasionally, a Hoover's sign (i.e. an uninhibited movement of the costal margin, away from the midline on the side of the injury) or unilateral abdominal paradox at the affected side is observed.

Bilateral paralysis occurs as part of severe generalized muscle weakness, but it may present as an isolated process, as the first manifestation of a more generalized neuromuscular syndrome with later involvement of other muscles. These patients often present with dyspnea on mild activity, especially during activity that requires expiratory muscle recruitment, like bending or lifting and sensing suffocation in the supine position.[52] A unique symptom is dyspnea with immersion in water due to decrease in VC of greater than 30%, as compared to less than 10% in normal individuals.[53] With disease progression dyspnea worsens and progressive hypercapnia and hypoxemia develop that are worse during sleep.

Diagnosis

i. *Clinical examination:* Under normal condition, expansion of the abdomen and rib cage occurs synchronously during inspiration, while in supine position there is greater expansion of the anterior abdominal wall during inspiration due to enhanced abdominal compliance. Diaphragmatic paralysis leads to the inward movement of the abdomen, as the rib cage expands during inspiration, a phenomenon known as paradoxical respiration.[54] These paradoxical motions can be detected noninvasively using magnetometry or respiratory inductance plethysmography.[55,56]

ii. *Pulmonary function:* For screening significant diaphragmatic impairment simpler test, like VC in upright and supine position may be used. In the supine position, due to reduced effectiveness of the intercostal muscle, secondary to expanded rib cage and abdominal contents encroaching upon the diaphragm, the VC decreases up to 10%. In bilateral diaphragmatic paralysis, characteristically the decreases in VC from erect to supine position is 30 to 55%.[57] Isolated diaphragmatic dysfunction may be suspected, if the predominant abnormality is a low PI max (lower than 60 cm H_2O) with relatively preserved PE max, however, a normal PI max due to the preserved strength of the accessory muscles may also be seen in these individuals.[58]

iii. *Maximal transdiaphragmatic pressure:* Contraction of the diaphragm lowers the intrathoracic pressure, while increases the intra-abdominal pressure. Pressure developed specifically by the diaphragm, can be measured as the difference between abdominal pressure, as assessed with a gastric catheter (Pga) and the pleural pressure, as assessed with an esophageal catheter (Pes). Transdiaphragmatic Pressure (Pdi) is then calculated as Pdi = Pga - Pes. The change in Pdi during normal tidal respiration and at TLC is typically 10 cm H_2O and above 30 cm H_2O, respectively and it can be increased to values greater than 150 cm H_2O during maximal inspiratory efforts (i.e. Muller maneuver).[59] Although Pdi specifically assesses diaphragmatic function, the requirement to place esophageal and gastric pressure transducers in patients with swallowing impairment and a complex procedure to generated maximum Pdi, obviates it as a useful maneuver.

iv. *Phrenic nerve stimulation:* The phrenic nerve is accessible transcutaneously for direct stimulation, either by electric or magnetic impulses as it traverses the neck.[60,61] In contrast to the electric impulse, which selectively stimulates phrenic nerve, magnetic impulses tends to stimulate cervical nerve roots as well that may activate rib cage muscles and give false positive results. Once stimulated both conduction time to assess the integrity of the phrenic nerve and Pdi to assess the mechanical output of the diaphragm can be measured. A conduction time of less than 9 ms and a twitch Pdi between is 25 and 35 cm H_2O is considered normal. Diaphragm mechanical output is measured as the magnitude of twitch Pdi.[62-64] Major disadvantage of phrenic nerve stimulation is the contraction history and dependence of twitch Pdi magnitude on the impedance of the abdomen and rib cage.

v. *Diaphragm imaging:* Chest radiography allows visualization of the elevated hemidiaphragms, but additional testing is required to exclude other pathologies. In addition, it also detects other pulmonary pathologies as a cause of respiratory symptoms. Fluoroscopy provides a real-time examination of diaphragm dome motion, best seen when both hemi diaphragms are visualized simultaneously in a lateral projection. A cephalad motion of diaphragm during inspiration is characteristic. Fluoroscopic sniff test, although sensitive and specific for unilateral diaphragm paralysis, is not sensitive for bilateral diaphragm paralysis. Kienback's sign is positive on fluoroscopy, if the affected diaphragm moves paradoxically upward with a vigorous sniff.[65,66] At least 2 cm of upward motion is considered abnormal.

Ultrasound with a 7 to 10 MHz transducer placed over the lower rib cage between the seventh and ninth intercostal spaces in the midaxillary line helps to visualize the diaphragm in the zone of apposition to the rib cage as well as the contraction of the diaphragm muscle itself. The diaphragm muscle in the zone of apposition is represented as a nonechogenic central structure bordered by two echogenic lines, the peritoneal and diaphragmatic pleurae.[67] Once visualized, diaphragm thickness (tdi) at end-expiration along with the change in tdi during inspiration can be measured. Changes in tdi during inspiration are proportional to diaphragm shortening in adults and infants, whereas tdi measured at end-expiration is proportional to diaphragm strength.[68-70] In patients with neuromuscular weakness, ultrasound to distinguishes between a functioning and a nonfunctioning diaphragm. With diaphragm paralysis, tdi is less than 2 mm and the diaphragm does not thicken during inspiration.[71]

Treatment

Most patients with diaphragm paralysis maintain adequate ventilation and gas exchange, by a compensatory increase in motor output to the intercostal muscles and increased output to the normal hemidiaphragm in patients with unilateral paralysis.[50,72]

In unilateral disease, main aim of treatment is exclusion of serious underlying intrathoracic pathology. Prognosis is good in patients with mild symptoms and routinely they don't need treatment.[50,51,73] In patients with disproportionate symptoms, surgical plication of the affected hemidiaphragm may provide excellent results.[74,75] Surgical plication causes improved lower lobe expansion and prevention of the paradoxical motion, leading to improved efficiency of remaining innervated respiratory muscles.

The treatment of bilateral diaphragmatic paralysis depends on the cause of the paralysis. In bilateral disease, in the absence of myopathy and preserved phrenic nerve, phrenic nerve pacing with radiofrequency signaling can be used.[76] Even in patients with nonfunctional phrenic nerve, if the intercostal nerve is functional and can be anastomosed, pacing can be done.[77] Once pacer is implanted, retraining the deconditioned diaphragm requires expertise and careful monitoring. Diaphragmatic pacing is limited by potential to fail abruptly, induction of diaphragm fatigue, upper airway obstruction and high cost, thus its use should be chosen considering all these factors.

In patients with nocturnal hypercapnia, some form of mechanical ventilatory support is required. Mechanical support can be provided by rocking bed, cuirass respirator, nasal Continuous Positive Airway Pressure (CPAP) or intermittent positive pressure ventilation by nasal mask and/or appliances.[78-81] With isolated diaphragm paralysis and no other neuromuscular impairment, Noninvasive Ventilation (NIV) is preferred to invasive mechanical ventilation.

Sleep Abnormalities in Neuromuscular Diseases

Sleep-associated breathing disorders in neuromuscular disease is fairly common, occurring in up to 42% of individuals.[82] Frequently nocturnal breathing abnormalities precede respiratory failure during wakefulness by months or even years.

In normal subjects, because of the withdrawal of the wakefulness drive to breathe, minute ventilation and oxyhemoglobin saturation (SaO_2) fall with the onset of sleep, whereas arterial carbon dioxide (CO_2) tension rises associated with reduction of number of protective reflex systems.[83] Physiologically, ventilation decreases by ±10% during sleep due to:[84,85]

1. Reduced wakefulness ventilatory drive stimulation at the respiratory centers
2. Reduced ventilatory response to chemical stimuli (hypercapnia and hypoxia)
3. Rapid Eye Movement (REM) sleep related muscle paralysis
4. Increased upper airway resistance due to reduced neural input to airway dilator muscles

In various neuromuscular diseases, distribution of respiratory muscle involvement dictates the nature of sleep associated breathing disorders. An obstructive defect is likely to predominate in patients with intact diaphragm, but upper airway or intercostal muscles are weak. In contrast, hypoventilation and gaseous exchange abnormalities will predominate in severe diaphragm dysfunction due to suppression of intercostal and accessory muscles in REM sleep.

Weakness of the pharyngeal muscle dilators, especially when the diaphragm is relatively spared causes generation of normal or increased negative intrathoracic pressure during inspiration that favors upper airway closure leading to obstructive events in these disorders. However, absent of chest wall movement due to severely weakened inspiratory muscles, these may be interpreted as central events despite continued inspiratory effort.[86] Additionally, pharyngeal neuropathy in neuromuscular disease may affect the normal stabilizing function of the pharyngeal muscles as well as the local reflex mechanisms that prevent upper airway collapse during inspiration.[87] Moreover, severe sleep apnea with hypoxemia has also been shown to induce axonal neuropathy.[88] In disorders characterized by significant bulbar involvement, such as Amyotrophic Lateral Sclerosis (ALS), weakness of the upper airway muscles has been thought to predispose to an increased incidence of obstructive sleep apnea.[89]

The most frequently reported discrete sleep breathing events in patients with respiratory muscle weakness are central hypopneas due to reduced tidal volume, which are more frequent and prolonged in REM sleep.[90,91] Inherent abnormalities of the ventilatory control may also be associated with neuromuscular diseases that reduce respiratory drive and ventilation via mechanisms unrelated to respiratory muscle weakness.

Screening sleep studies have been recommended in patients with neuromuscular disease, often guided by serial daytime respiratory function tests (typically spirometry plus/minus blood gases).[92] The gold standard for identifying breathing and other abnormal events during sleep is the Polysomnogram (PSG).

Pulmonary Involvement in Tropical Diseases

S Jain, SK Jindal

INTRODUCTION

Tropical diseases encompass all those conditions that occur solely, or principally, in the tropics. In practice, the term is often taken to refer to infectious diseases that thrive in hot, humid climatic conditions. Many of these diseases involve the lungs directly or indirectly through various mechanisms. The vivid clinical features pose problems in the differential diagnosis of pulmonary diseases. This is especially so when such a condition, being uncommon, is not routinely recognized in a particular geographical region or a country. The involvement may also have adverse effects on the prognosis of the disease and in turn lead to increased mortality.

Theoretically, almost any tropical infection can involve the respiratory system (Table 164.1), but a few which are more common and important are included in this chapter. Many other important conditions have been discussed in other chapters.

TABLE 164.1: Tropical infections that commonly involve the respiratory system

- BACTERIAL – Pneumonias, Tuberculosis, Enteric Fever
- FUNGAL – Aspergillosis, other fungal pneumonias
- VIRAL - Hanta virus, Dengue, Influenza
- PARASITIC – PROTOZOAL- Malarial parasites, *E. histolytica*, *L. donovani*, *T. gondii*, Babesia
- HELMINTHIC – E. granulosus, Filariasis, Schistosomiasis, A. lumbricoides

MALARIA

Malaria is a very important cause of mortality in the developing countries. Apart from classical presentation of fever with chills and malaise, it may present with respiratory and other systemic manifestations. Important time may be lost in such cases in instituting antimalarials due to late diagnosis, leading to higher morbidity and mortality. Pulmonary involvement occurs in 3 to 10% cases, most commonly in malaria due to *Plasmodium falciparum*.[1] Different clinical forms of pulmonary complications have been described in malaria (Table 164.2). Three types of pulmonary involvements were known in malaria in the past: bronchitic, pneumonic and bronchopneumonic.[2] However, more definitive involvements are now recognizable.[3-7]

Acute Respiratory Distress Syndrome (ARDS)

Pulmonary edema is common in patients with hyperparasitemia, renal failure and pregnancy and is

TABLE 164.2: Important pulmonary complications of malaria

   - Nosocomial

iv. Acute asthma like presentation

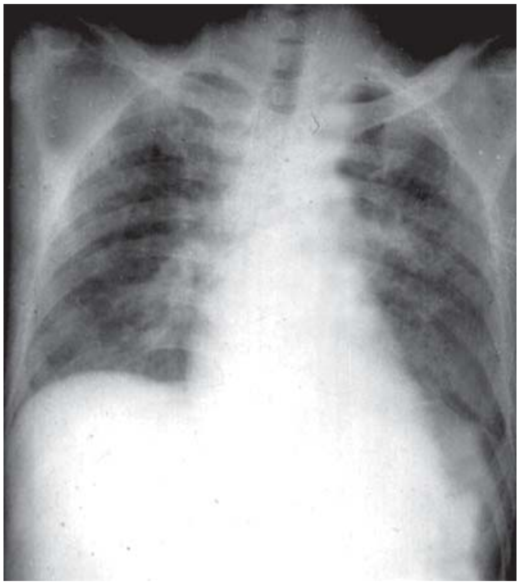

Fig. 164.1: Pulmonary edema of non-cardiogenic origin in a patient of malaria due *P. falciparum* infection

commonly associated with hypoglycemia and metabolic acidosis. It may develop suddenly after delivery, due to fluid overload. Pulmonary edema is the terminal event in many cases of fatal falciparum infection (Fig. 164.1). Cerebral edema is commonly present in these cases. Pulmonary edema was seen in 21% of patients of cerebral malaria of whom 40% fulfilled the ARDS criteria.[8] It was reported in 30% of intensive care unit patients admitted with severe malaria.[9] Incidence of pulmonary edema in malaria from India has been described in several studies in up to 20% of patients.[10-15] Pulmonary edema has been rarely described in patients with *Plasmodium ovale* and *Plasmodium vivax* infections.[16-20] The first indications of impending pulmonary edema include tachypnea and dyspnea, followed by hypoxemia and respiratory failure requiring intubation.

It can also develop in patients with normal capillary wedge pressures. Such cases may happen due to the increased permeability of pulmonary capillaries. It is generally produced by a disturbance in the pulmonary microcirculation. Sequestration of red cells, hypoalbuminemia, clogging of pulmonary microcirculation and disseminated intravascular coagulation with immune complex disease may also play their role in the pathogenesis. A central mechanism with hypothalamic dysfunction due to disturbed oxidative metabolism leading to pulmonary venular spasm has also been suggested.

The most severe form is acute pulmonary edema, which manifests with acute respiratory distress, is rapidly progressive and occurs in the absence of cardiac decompensation or fluid overload. It has been proposed that *P. vivax* infected erythrocytes may sequester within the pulmonary microvasculature and cause greater inflammatory response to a given parasite burden than with *P. falciparum*.[21] A longitudinal study in patients with uncomplicated (n=50) and severe falciparum malaria suggested persistent pulmonary vascular occlusion in both types of patients, likely from sequestration of red and white blood cells; severe malaria patients however, had persistent impairment of alveolar-capillary membrane dysfunction.[22] Refractory to the usual treatment of cardiogenic pulmonary edema, it has a high mortality with up to 50% of the patients succumbing to the complication. The mechanism of pulmonary edema is not clearly understood. It has a close resemblance to adult respiratory distress syndrome. Multiple mechanisms have been hypothesized. Over-hydration has been proposed as the cause in some cases of pulmonary edema. This, compounded by venous and lymphatic obstruction, leads to elevated capillary wedge pressure.

Other Manifestations

Acute asthma like picture has been also described.[7] Clinical features may develop rapidly, even after initial response to antimalarial treatment and clearance of parasitemia. The various pulmonary symptoms of malaria include cough (80%), dyspnea (40%), expectoration (32%), chest pain (18%) and hemoptysis (4%). The common signs are tachypnea, tachycardia and hypotension.[8] Chest radiographic abnormalities range from confluent nodules to basilar and/or diffuse bilateral pulmonary infiltrates. Benign forms have rarely been described in the literature. These cause minimal or no respiratory difficulty, and can present as pleural effusions, interstitial edema and lobar consolidation. They often go undiagnosed and unrecognized as part of the clinical and radiologic spectrum of acute malaria, and are probably more common than reported.

Postmortem studies of the lungs have grossly revealed congested, edematous lungs with frequent serosanguinous effusions. Typically, the effusions are transudative and negative on culture. Microscopic findings include large pigmented phagocytes in dilated septal capillaries, thickened alveolar septae, micro hemorrhages, hyaline membranes and diffuse alveolar edema.

Management

Treatment for respiratory complications need urgent attention. Fluid overload should be avoided at all costs,

TABLE 164.3: Recommendations for treatment of severe and complicated malaria (National Drug Policy on Malaria, 2008; Director of National Vector Borne Disease Control Programme, Delhi)

Parenteral artemisinin derivatives (for nonpregnant women) or quinine should be used irrespective of chloroquine resistance status of the area. However, the guidelines for specific antimalarial therapy as per the World Health Organization recommendation are given below:

- **Quinine salt** 20 mg/kg* body weight (bw) on admission (IV infusion or divided IM injection) followed by maintenance dose of 10 mg/kg bw 8 hourly; infusion rate should not exceed 5 mg salt/kg bw per hour.
  (*loading dose of Quinine salt, i.e. 20 mg/kg bw on admission may not be given if the patient has already received quinine or if the clinician feels inappropriate).
- **Artesunate:** 2.4 mg/kg bw IV or IM given on admission (time = 0), then at 12 h and 24 h, then once a day.
- **Artemether:** 3.2 mg/kg bw IM given on admission then 1.6 mg/kg bw per day.
- **Arteether:** 150 mg daily IM for 3 days in adults only (not recommended for children).

especially in pregnant women. The central venous pressure should be maintained between 0-5 cm of H_2O by regulating fluid intake and nursing the patient propped up at 45°. All intravenous fluids should be stopped immediately and diuretics may have to be administered. Initial management of pulmonary edema includes treatment with oxygen, back-rest and diuretics if there is evidence of fluid overload. Injectable furosemide (40 mg intravenously) increased to 200 mg in the absence of a desired response is generally used. Fluid volume can be further reduced by venesection and letting of 250 ml of blood initially. This blood or its packed cells can be retransfused once the problem settles down. The procedure can be repeated carefully if needed.

If the patient deteriorates with conservative treatment, mechanical ventilation is indicated. Treatment in such a condition, is provided as for any other patient of acute respiratory distress syndrome. Drugs like corticosteroids are not of any proven benefit in the management of these cases. Noninvasive ventilation used for the management of acute lung injury/ARDS associated with vivax malaria has been shown to be associated with good outcome.[23]

Antimalarial treatment in addition to the respiratory support is an important component of overall management. Detailed guidelines for treatment have been provided as per National Drug Policy on Malaria (2008) in India (Table 164.3).[24] Antibiotics, bronchodilators and other symptomatic treatments are required depending upon the presence of complications. Antimalaria drugs like mefloquine are occasionally associated with pulmonary complications such as pneumonitis.[25]

TYPHOID

Typhoid is a systemic febrile illness caused by Salmonella typhi. The estimated prevalence globally is around 21.6 million cases per year and 216,500 deaths worldwide in 2000.[26] The incidence in developing countries is 540 cases per 100,000 while in the developed countries it is reported in about 0.2 cases per 100,000 population.[27] It develops due to the consumption of contaminated food and water or contact with chronic infected carrier.

The involvement of lung in typhoid fever is not an uncommon entity (Table 164.4). The exact pathogenesis is not known. It was long back in 1885 when Artaud noticed typhoid like bacilli in lungs of patient with pulmonary apoplexy. Because of hematogenous spread of the organism, it has been long tried to isolate the organism from the lungs.[28] The endotoxin released from organism is considered responsible for the signs and symptoms of pulmonary disease. Predisposing factors for lung involvement include, but are not limited to immunocompromised host, alcoholism, sickle cell disease or preexisting pulmonary disease. Fever, toxaemia and abdominal pain are the most common manifestations of typhoid fever, while 10 to 15% of the patients with illness lasting more than two weeks develop systemic complications.

Pleuropulmonary complications are the most common extraintestinal manifestations.[29] The incidence

TABLE 164.4: Pulmonary complications of important tropical infections

Enteric fever
1. Typhoid bronchitis
2. Pneumonia and sepsis
3. Acute respiratory distress syndrome

2. Severe pulmonary hemorrhage

Amebiasis
1. Pulmonary amebiasis (Pneumonia, Empyema)
2. Hepatobronchial/ hepato-bronchopleural fistula

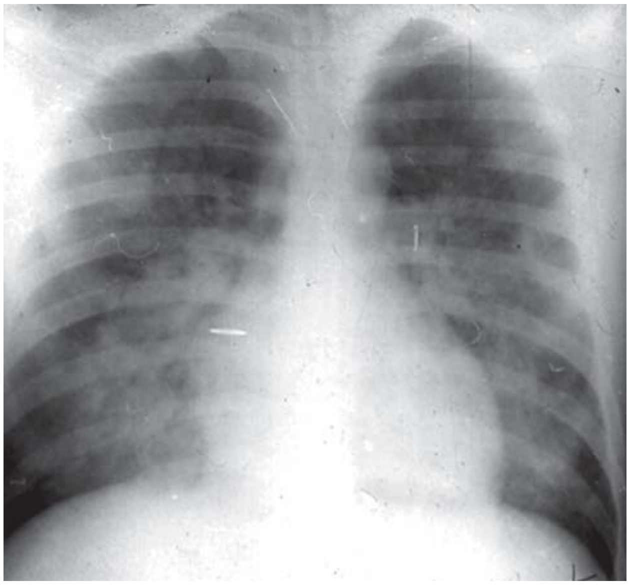

Fig. 164.2: Pulmonary edema with normal cardiac shadow in a patient of enteric fever presenting with acute respiratory distress

of pulmonary manifestations ranges from 1 to 7%. In one study of 65 cases of typhoid involving lungs, the incidence was found to be 6.2%. The chief symptoms and signs included cough (86%), crackles (64%), coryza (60%), chest pain (60%) and pleural effusion (5%). Pneumonia is uncommon (1%) but can occur in 50% of patients with empyema, bronchopleural fistula, lung abscess or effusion. It is one of the various life-threatening complications of typhoid fever. Bronchopneumonia is more common, although lobar pneumonia may also be seen rarely in these patients. In advanced disease, secondary bacterial pneumonia may occur due to aspiration or other organism. Reports of ARDS, occurring in typhoid fever has been also reported (Fig. 164.2).[30-32] In most patients, ARDS manifests in the early phase, i.e. first two weeks of illness.[32]

Nonspecific radiographic infiltrates are seen in one-fourth of the patients with pulmonary symptoms. It is rare to isolate salmonella from the sputum though blood culture may be positive in majority, which is the best test to diagnose salmonellosis. Occasionally, lung abscess caused by salmonella typhi, sometimes in a preexisting hydatid cyst has been reported.[33,34]

The treatment of typhoid involves the appropriate and timely use of antibiotics along with supportive respiratory care. Steroid use decreases the mortality from typhoid fever.[32] Outcome of ARDS is frequently fatal. Ventilatory and other supportive care are crucial to management.[30]

LEPTOSPIROSIS

Leptospirosis caused by Leptospira interrogans, is a reemerging zoonosis occurring as large outbreaks throughout the world.[35] This is especially so in the Asian countries with an enormous load of diseases with tropical pathogens.[36] The natural reservoirs are the mammals (rodents, cattle, dogs, horses, sheep) with humans getting incidentally infected after contact with contaminated animal urine. Risk factors include outdoor activities like walking barefoot, gardening and forest activities. Wet soil, refuse around the home, pets at home, and skin wounds may also help in promoting the spread of disease.

Leptospirosis can manifest with variable clinical picture ranging from mild subclinical illness to multi-organ failure (Table 164.4). The incidence of lung involvement in leptospirosis ranges from 20 to 70%, often goes as an unrecognized illness poses difficulties in management of complicating problems which sometimes are fatal.[37-40] Pulmonary involvement is often mild, but for the severe pulmonary hemorrhage that are sometimes described.[40-43] The pathophysiology of pulmonary hemorrhages is unclear and probably related to vascular injury and focal hemorrhages.[44] The incidence of pulmonary hemorrhage seems to increase in the recent reports.

The etiology of pulmonary hemorrhages is probably multifactorial.[37,39] It could possibly be sepsis related with disturbed platelet function.[37] Linear definition of immunoglobulin and complement on the alveolar surfaces may play a role in causing hemorrhages.[45] Two mechanisms related to damage have been proposed: one, toxin-mediated capillary vasculitis and second, the immune mediated damage by host. Leptospira are found in a lesser number than in the liver suggesting that the toxins generated by the liver circulate in the body and cause damage at a distant site. Leptospira can disseminate due to its ability to penetrate tissue without being inhibited by immune cells. Outer membrane protein of leptospira is the most important for toxin-mediated damage. Peptidogylcans activate vascular endothelial cells to increase their adhesiveness for neutrophils and may be involved in mediating local and systemic inflammation. Cytokines like Tumor Necrosis Factor-Alpha (TNF-α) may also play some role in causing damage. Immune-mediated damage depends on the antibody production against the Lipopolysaccharide (LPS) antigen of the cell wall. It influences the severity of the disease.

Respiratory symptoms could occur during both the anicteric and the icteric phases, include hemoptysis, chest pain, cough and dyspnea. Acute respiratory distress syndrome is a serious complication with high rates of mortality.[41,42,46] Severe pulmonary form of leptospirosis (SPFL) appears in four to six days of illness, is the most serious form with deaths (30 to 60%) occurring within 72 hours. Chest radiographs may show small nodular densities (57%), confluent consolidation (16%) or a ground glass appearance (27%).[47] High resolution computed tomography chest delineates the picture better. It may show ground glass opacities, pleural effusion or consolidation. Sometimes, chest manifestations occur pre-terminally and suddenly.[48] It is therefore, important to keep a strict vigil for the problems in patients with severe leptospirosis.

It often goes unnoticed because of the lack of clinical suspicion, varying clinical presentation and lack of adequate molecular diagnostic facilities.[38] Diagnostic tests like Dot test or Enzyme-Linked Immunosorbent Assay (ELISA) for leptospira immunoglobin M (IgM) antibody and Polymerase Chain Reaction (PCR) for 16s rRNA on blood and urine samples are used for confirmation. Pulmonary involvement and hemoptysis is shown as a strong predictor of mortality in patients with severe leptospirosis.[49]

The treatment of leptospirosis should be initiated early based on epidemiological and clinical features to shorten the illness, and because respiratory involvement needs urgent care. Besides the supportive care, plasma exchange with immunosuppression is shown to improve survival in the presence of pulmonary hemorrhage.[38,50] Activated protein C was shown to be helpful in sepsis attributed to dual infection with *P. falciparum* and leptospirosis.[51] Assisted ventilation should be started at the first sign of clinical suspicion of respiratory failure.

DENGUE

Dengue fever is a common tropical illness leading to high morbidity in the developing countries. It was identified as the most common cause of systemic febrile illness among travelers to the developing countries. It is an endemic illness especially in the countries of Africa, Southeast Asia and the Eastern Mediterranean. It presents with a wide range of manifestations ranging from mild illness to a severe shock-like state. It is caused by dengue virus, which is a Flavivirus, spread by the bite of Aedes mosquito.

There are four serotypes of dengue virus (DENV-1 to 4). Infection with one serotype leads to classic dengue fever with lifelong immunity to that serotype. Infection with second serotype leads to dengue hemorrhagic fever with severe manifestations.[52] There are only a few case reports of respiratory involvement in Dengue Hemorrhagic Fever (DHF). It may manifest with cough, sore throat or nasal congestion. Pneumonitis or pleural effusion may develop as reactive phenomena.[52,53] Hemoptysis has been reported to develop in 1.4% and pulmonary hemorrhages occur in a small number of cases. Pulmonary hemorrhages may present with mild hemoptysis and bilateral areas of consolidation on chest roentgenogram.[54-56] Sometimes, the hemorrhages are rather fatal.[57,58] Occassionally dengue can also present with ARDS like picture.[59]

The development of clinical manifestations is related to pulmonary capillary leak. Dengue virus causes endothelial cell dysfunction. The virus attaches to the endothelial surface, may serve as target for antibody binding and complement activation. Cytokines like TNF-α, IL-8, IFN-γ and free VEGF have been observed in patients with DHF. Besides this, abnormalities in the coagulation cascade, thrombocytopenia, platelet dysfunction, disseminated intravascular coagulation and vascular defects all play a role in the development of DHF.

Radiologically, pulmonary hemorrhages are seen as ground glass opacities. There may be pleural effusion, associated consolidation and diffuse infiltrates in the lung fields. Hemagglutination Inhibition (HI) assay remains the gold standard serologic test for dengue virus-specific antibodies. Immunoglobulin M assay for dengue virus is less sensitive and specific than HI assay and becomes positive only after 10 to 14 days of acute phase. The dengue viral Nonstructural Protein 1 (NS1) can be detected in plasma, especially during the first five to six days of illness, high levels early in infection were associated with DHF.

Treatment of DHF with pulmonary manifestations is primarily supportive. There is no specific therapy for DHF. Careful early intervention with appropriate intensive care can decrease the mortality to less than 1%.

AMEBIASIS

It is a caused by a protozoan *Entamoeba histolytica* that is endemic in the developing countries and responsible for high morbidity and mortality. Transmission occurs by the consumption of contaminated food and water or oro-anal contact. The infectious form is the cyst which after being ingested, excysts in the lumen of intestine, converts to trophozoite, attach to the wall of the intestine causing symptoms. As is well known, it causes gastrointestinal manifestations ranging from diarrhea to severe colitis with bloody diarrhea.[3] Extraintestinal manifestations occur mainly in the liver as abscess formation, which can spread to lung tissue. It can manifest as reactionary pleural effusion or the abscess may rupture into the lung parenchyma causing respiratory distress, empyema and lung abscess development.[60-62] Hematogenous spread to the lung may also occur. There may be sputum production ranging from mild to copious. Rarely, superior vena cava syndrome due to pulmonary amebiasis is reported.[63] If hepatobronchial fistula develops, sputum may be purulent with an anchovy sauce appearance. There is no eosinophilia and jaundice is uncommon.

The diagnosis of amebiasis rests on detection of trophozoites or cysts in the stool. It is not a very sensitive or specific test for extraintestinal manifestations. Antigen detection in the stool or pus is more reliable for *Entamoeba histolytica*. Most patients develop antibodies against *E. histolytica,* which can be detected in the serum. Immunoglobulin M antibody detection is a useful test for acute infection. Immunoglobulin G antibodies may be detected years after active infection, its presence does not indicate active disease. Metronidazole or tinidazole are highly effective for intestinal or extraintestinal manifestations. To prevent recurrence, luminal agents like iodoquinol are effective. Mild pleural effusion does not require treatment. Drainage along with anti-amoebic antibiotics is necessary to manage a lung abscess or empyema to prevent complications.

Pulmonary involvement can occur in several other tropical infections either in isolation or along with other system manifestations. Several such syndromic manifestations are region specific described in different parts of the world. Readers are advised to refer to different chapters of this book or other specific texts for details on conditions of interest.

Pregnancy and Pulmonary Diseases

Lakhbir K Dhaliwal, Preeti Verma

Hormonal changes in pregnancy cause significant alterations in pulmonary physiology, which are important to understand for the interpretation of diseased state. A number of pulmonary disorders are encountered during pregnancy.

PULMONARY PHYSIOLOGICAL CHANGES DURING PREGNANCY

Changes in upper respiratory tract include hyperemia, mucosal edema, hypersecretion and increased mucosal friability. These are attributed to the presence of tissue edema, capillary congestion and hyperplasia of mucous glands, due to the estrogen effect. The enlarged uterus pushes the diaphragm upwards by as much as 4 cm, the anteroposterior and transverse diameter of thorax increases. Diaphragmatic function remains normal. Lung volumes and lung capacities are significantly altered during the pregnancy (Table 165.1).[1]

TABLE 165.1: Lung function changes during pregnancy

- Vital capacity and inspiratory capacity - increase by 20% in late pregnancy.
- Expiratory reserve volume - decreases from 1,300 ml to approximately 1,100 ml.
- Tidal volume - increases by approximately 40%.
- Respiratory rate remains constant.
- Minute ventilation - increases by about 30 to 40%.
- Arterial pO_2 increases from 100 to 105 mm Hg.
- Carbon dioxide production increases by approximately 30%, but because of an increase in the diffusion capacity and the alveolar hyperventilation, the pCO_2 decreases from 40 to 32 mm Hg.
- Residual volume decreases by approximately 20% (from 1,500 ml to approximately 1,200 ml).

The enlarged uterus and the increased abdominal pressure cause chest wall compliance to reduce by a third. Thus the functional residual capacity (the sum of expiratory reserve and residual volume) decreases by 10 to 20%. Pregnancy does not appear to change the lung compliance, but chest wall and total respiratory compliance are reduced at term. Basal oxygen consumption increases incrementally by 20 to 40 ml/min in the second half of pregnancy. There is physiological hyperventilation that results in increased kidney bicarbonate excretion. Serum levels of bicarbonate decrease to approximately 15 to 20 mEq/L, which leads to slightly alkalotic pH at 7.45.

Dyspnea During Pregnancy

Dyspnea is commonly seen in around 60% of women during pregnancy. It is physiological, occurs early in pregnancy and does not interfere with daily activities. The increased progesterone level leading to hyperventilation is thought to be the most important mechanism. This physiologic dyspnea should be differentiated from breathlessness caused by disorders complicating pregnancy. The patient should be carefully evaluated. The presence of other symptoms and signs of cardiopulmonary disease indicate a possible pathologic nature of dyspnea, which needs careful evaluation.[2]

Asthma in Pregnancy

Asthma affects between 3% and 12% of pregnant women worldwide. The prevalence among the pregnant women seems to rise. It is a well recognized fact that women with asthma are at risk for poor pregnancy outcomes.[3]

Pathophysiology

The pathophysiology of asthma is complex. It has a major hereditary component. Airway inflammation, intermittent airflow obstruction and bronchial hyperresponsiveness are the major factors. The presence of airway edema and mucus secretion also contributes to airflow obstruction and bronchial reactivity.

The presence of airway hyperresponsiveness or bronchial hyperreactivity in asthma is an exaggerated response to numerous exogenous and endogenous stimuli. The stimulus can be caused by different allergens, viral infections, aspirin, cold air and exercise. Clinical course of asthma ranges from mild wheezing to severe bronchoconstriction. Asthma may be clinically classified according to the frequency of symptoms, Forced Expiration Volume in one second (FEV_1) and peak expiratory flow rate.[4]

Effect of Pregnancy on Asthma

The effects of pregnancy on asthma are variable; 23% improve and 30% become worse during pregnancy, intrapartum exacerbation is seen in 20% of patients.[5] Maternal morbidity seen with asthma is around 2.3% in mild, 19.3% in moderate and 26.9% in severe asthma, requiring hospitalization during pregnancy for asthma exacerbations.[6] In one of the large prospective studies, approximately each one-third patients improved, remained unchanged, or clearly worsened.[7] If asthma is going to worsen, it will usually do so between 24 and 36 weeks of gestation. Symptoms are likely to be less troublesome in the peripartum period. In most women, asthma severity returns to the prepregnant state within three months of delivery, but in rare cases it may be worse than before the pregnancy.[8,9]

Effect of Asthma on Pregnancy

In the recent years, pregnancy outcome in asthmatic women has improved. Clinical features are the same as in the non-pregnant state. Earlier studies on the effects of asthma on pregnancy reported inconsistent findings with regard to perinatal mortality, pre-eclampsia, preterm birth, hemorrhage and low birth-weight.[10-12] However, in a recent study, it is concluded that severe disease affects the pregnancy outcome.[13] There is increased risk of pre-eclampsia, preterm labor, placental abruption, preterm rupture of membranes, low birth-weight infants and perinatal mortality.[13,14] Asthma medication and poor asthma control leading to hypoxia, have been hypothesized to explain these observations.[15]

In a recent European study, the risks of obstetrical complications were not higher in asthmatic pregnant women than in non-asthmatics except for depression, miscarriage and cesarean delivery.[16] There are some data to support a correlation with poor asthma control indicated by increased hospitalization for exacerbations and decreased FEV_1 values directly proportional to low birth-weight and ponderal index and inversely to gestational hypertension and preterm delivery.[5,15,17] Most of the literature available till date shows that patients with more severe asthma may have the greatest risk for complications during pregnancy, whereas better controlled asthma is associated with decreased risks.[5,15,18-21] In status asthmaticus, muscle fatigue with respiratory arrest, pneumothorax, pneumomediastinum, acute cor pulmonale and cardiac arrhythmias can occur, which can often be life threatening.

The fetus, dependent for its oxygen supply on maternal arterial oxygen content, exists in a precarious state of oxygenation. Compensatory mechanisms of the fetus to combat potentially adverse conditions of oxygenation include a hemoglobin level of atleast 16 g/dl and a P_{50} of 22 mm Hg. With reasonable control of asthma, perinatal outcomes are generally good. Poorly controlled asthma or severe asthma attacks further threaten the fetus because of increased maternal hypoxemia and diminution of uterine artery blood flow, secondary to hypocapnic vasoconstriction and an alkaline induced leftward shift of oxyhemoglobin dissociation curve. These fetuses have increased the incidence of intrauterine growth retardation, low birth-weight, prematurity and neonatal hypoxia.[5,15,19]

The possible teratogenic and adverse effects of drugs in asthma are important concerns. However, there is enough evidence that the commonly used drugs cause no harm to fetus.[22-24]

Management of Chronic Asthma

The management of asthma during pregnancy should be aggressive, with the aim of eliminating symptoms, restoring and maintaining normal lung function. Cooperation between the respiratory physician and obstetrician is important throughout pregnancy for women with severe asthma. The guidelines by the Working Group on Asthma and Pregnancy recommend a multipronged approach to management (Table 165.2).[4]

TABLE 165.2: Components of asthma management during pregnancy

- Patient education
- Avoidance or control of environmental precipitating factors
- Objective assessment of pulmonary function and fetal well-being
- Pharmacological therapy to provide baseline control and treat exacerbations

Objective Measures for Assessment and Monitoring

Subjective measures of lung function by the patient and physician provide an insensitive and inaccurate assessment of airway hyperresponsiveness, airway inflammation and asthma severity. The FEV_1 following a maximal inspiration is the single best measure of pulmonary function. However, repeated measurement of FEV_1 is generally impractical. The Peak Expiratory Flow (PEF) correlates well with the FEV_1 and has the advantages that it can be measured reliably with inexpensive, disposable, portable peak flow meters. Patient self-monitoring of PEF provides valuable insight to the course of asthma throughout the day, assesses circadian variation in pulmonary function and helps to detect early signs of deterioration so that timely therapy can be instituted. The FEV_1 ideally is >80% of predicted. For PEF, predicted values range from 380 to 550 L/min.[25]

Asthma Pharmacotherapy

The goal of asthma therapy is multiphasic: (1) to relieve bronchospasm, (2) to protect the airways from irritant stimuli, (3) to prevent the pulmonary and inflammatory response to an allergen exposure, and (4) to resolve the inflammatory process in the airways, leading to improved pulmonary function with reduced airway hyperresponsiveness. Although it is assumed that asthma medications are as effective in pregnant as in non-pregnant patients, differences in maternal physiology and pharmacokinetics may affect the absorption, distribution, metabolism and clearance of medications during pregnancy. Endocrinologic and immunologic changes during pregnancy include elevations in free plasma cortisol, possible tissue refractoriness to cortisol and changes in cellular immunity.[26,27]

Inhaled β_2-Agonists

Beta$_2$-agonists are currently recommended for use with all the degrees of asthma during pregnancy.[28,29] The commonly used inhaled β_2-agonists are salbutamol (albuterol), terbutaline, fenoterol and long-acting agents like salmeterol and formoterol. Salbutamol is preferred because of the availability of more human data on safety. It has the advantage of a rapid onset of effect in the relief of acute bronchospasm through smooth muscle relaxation. Side effects include tremors, tachycardia and palpitations, associated with an increased risk of death with chronic use.[30,31] β_2-agonists appear to be safe, based on a review of six published studies with 1,599 women with asthma who took β_2-agonists during pregnancy.[28] Additionally, in a large prospective trial, they were not associated with adverse pregnancy outcomes.[32]

Inhaled Corticosteroids

They are the mainstay of treatment in moderate to severe asthma and appear to have a good safety profile in pregnancy.[28] The use of inhaled corticosteroids among non-pregnant asthmatics has been associated with a marked reduction in fatal and near-fatal asthma. Inhaled corticosteroids produce clinically important improvements in bronchial hyperresponsiveness that appear to be dose related.[33] The National Asthma Education and Prevention Working Group reviewed 10 studies, including 6,113 patients who took inhaled corticosteroids during pregnancy for asthma. Based on these studies, there was no evidence of any increase in congenital malformations or adverse perinatal outcomes with inhaled corticosteroid use.[28] Data are available describing budesonide use during pregnancy than with other inhaled corticosteroids. Budesonide is considered as a preferred medication, but if a woman is well-controlled by a different inhaled corticosteroid before pregnancy, it seems reasonable to continue that medication during pregnancy. All inhaled corticosteroids are currently labeled Food and Drug Administration (FDA) pregnancy class C, except budesonide, which is class B.

Theophylline

Theophylline is a methylxanthine with various anti-inflammatory actions that may potentiate the efficacy of inhaled corticosteroids.[34,35] New dosing guidelines have recommended that serum theophylline concentrations be maintained at 5 to 12 mcg/ml during pregnancy.[28] Symptoms of adverse theophylline effects, including insomnia, heartburn, palpitations and nausea, may be difficult to differentiate from typical pregnancy symptoms. High doses have been observed to cause jitteriness, tachycardia and vomiting in mothers and neonates.[36,37]

The main advantage of theophylline is the long duration of action, which is especially helpful in the management of nocturnal asthma.[38] Theophylline may be employed as an alternate treatment when β_2-agonists and inhaled anti-inflammatory agents do not adequately control symptoms. Indicated only for chronic therapy, it is not effective for the treatment of acute exacerbations during pregnancy.[39] In a recent randomized controlled trial, there were no differences in asthma exacerbations or perinatal outcomes in a cohort receiving theophylline compared with the cohort receiving inhaled beclomethasone. However, the theophylline cohort had significantly more side effects and instances discontinuation of study medication.[20]

Leukotriene Moderators

Treatment with leukotriene receptor antagonist montelukast has been shown to significantly improve pulmonary function as measured by FEV_1. The leukotriene receptor antagonists, zafirlukast and montelukast are both pregnancy category β drugs.[31] There are minimal data regarding the efficacy or safety of these agents during human pregnancy.

Oral (Systemic) Corticosteroids

The National Asthma Education and Prevention Working Group reviewed eight human studies, including one report of two meta-analyses.[28] Most of the subjects in these studies did not take oral corticosteroids for asthma. The Panel concluded that findings from the current evidence review were conflicting. Oral corticosteroid use during the first trimester of pregnancy was associated with a three-fold increased risk for isolated cleft lip with or without cleft palate, with a background incidence of about 0.1%; the excess risk attributable to oral steroids would be 0.25 to 0.3%.[40]

Because of the definite risks of severe uncontrolled asthma both to the mother and the fetus, the Working Group recommends the use of oral corticosteroids when indicated for the long-term management of severe asthma or for severe exacerbations during pregnancy.

Cromolyn and Nedocromil

Cromolyn and nedocromil, both inhibit mast cell degranulation. Cromolyn, which is virtually devoid of significant side effects, blocks both the early- and late-phase pulmonary response to allergen challenge, as well as prevents the development of airway hyper-responsiveness.[49] Both are ineffective for acute asthma. They are less effective than inhaled corticosteroids in reducing the objective and subjective manifestations of asthma. Cromolyn appears to be safe during pregnancy.[32]

Antenatal Management

Patients with moderate and severe asthma should be considered at risk for pregnancy complications. Adverse outcomes can increase by the underestimation of asthma severity and under treatment of asthma exacerbations. The first prenatal visit should include a detailed medical history with attention to medical conditions that could complicate the management of asthma. The patient should be questioned about the presence and severity of symptoms, episodes of nocturnal asthma, the number of the days of work missed due to asthma exacerbations, history of acute asthma emergency care visits and smoking history. The type and amount of asthma medications, including the number of puffs of β_2-agonists used each day should be recorded.

Gravidas with moderate or severe asthma should have scheduling of prenatal visits based on clinical judgement. In addition to routine care, monthly or more frequent evaluations of asthma history and pulmonary function (FEV_1 or PEF) are recommended. Those with mild and well-controlled asthma may receive routine prenatal care. Patients should be instructed on proper dosing and administration of asthma medication. The least number of medications needed to control asthma symptoms should be used.

Moderate and severe asthmatics should have additional fetal surveillance in the form of ultrasound examinations and antenatal fetal surveillance. Because asthma has been associated with intrauterine growth restriction and preterm birth, it is necessary to accurately establish pregnancy dating. Ultrasound examinations are also needed to evaluate fetal viability, anatomy, amniotic fluid volume, placental location and interval fetal growth. The intensity of antenatal fetal surveillance should be based upon the severity of asthma.

Management of Acute Asthma

The treatment of acute asthma is same as in non-pregnant state. The principal goal should be the prevention of hypoxia. Continuous fetal monitoring should be initiated if gestation has advanced to the point of potential fetal viability. First line of therapy is β-agonists, such as terbutaline, salbutamol, isoetharine, epinephrine, isoproterenol or metaproterenol, which are given subcutaneously, orally, or in inhaled forms. Salbutamol (2.5 to 5 mg every 20 minutes for three doses, then 2.5 to 10 mg every 1 to 4 hours as needed, or 10 to 15 mg/hour continuously) should be delivered by nebulizer, driven with oxygen.[28] Occasionally nebulized treatment is not effective when terbutaline, 0.25 mg can be administered subcutaneously every 15 minutes for three doses. The patient should be assessed for the general level of activity, color, pulse rate, use of accessory muscles and airflow obstruction determined by auscultation and FEV_1 or PEF before and after each bronchodilator treatment. Measurement of oxygenation through pulse oximeter or arterial blood gases is essential. Arterial blood gases should be obtained if oxygen saturation remains less than 95%; chest radiographs are not commonly needed. Assessment to treatment is assessed as good, incomplete or poor (Table 165.3).

TABLE 165.3: Assessment of response to initial treatment of acute asthma

Good Response

- FEV_1 or PEF >70%
- Response sustained 60 minutes after last treatment
- No distress
- Physical examination: normal
- Reassuring fetal status
- Discharge home

Incomplete Response

- FEV_1 or PEF 50% but <70%
- Mild or moderate symptoms
- Continue fetal assessment until patient stabilized
- Monitor FEV_1 or PEF, O_2 saturation, pulse
- Continue inhaled salbutmol and oxygen
- Inhaled ipratropium bromide
- Systemic (oral or intravenous) corticosteroid
- Individualize decision for hospitalization

Poor Response

- FEV_1 or PEF <50%
- P_{CO_2} >42 mm Hg
- Physical examination: severe symptoms, drowsiness, confusion
- Admit to hospital intensive care
- Continue fetal assessment

Status Asthmaticus and Respiratory Failure

Severe asthma of any kind not responding after 30 to 60 minutes of intensive therapy is termed as status asthmaticus. Early intubation and mechanical ventilation may be needed. Management in intensive care has resulted in good outcome.[42]

Labor and Delivery Management

Asthma medications should not be discontinued during labor and delivery. The patient should be kept hydrated and receive adequate analgesia in order to decrease the risk of bronchospasm. If systemic corticosteroids have been used in the previous four weeks, then intravenous corticosteroids, hydrocortisone 100 mg q 8 hours should be administered during labor and for the 24-hour period following delivery to prevent adrenal crisis.[28]

It is rarely necessary to perform a cesarean delivery for an acute asthma exacerbation. Usually, maternal and fetal compromise will respond to aggressive medical management. Oxytocin and prostaglandin (PG) E_2 or E_1 can be used for cervical ripening and induction. Postpartum hemorrhage is treated with oxytocin and prostaglandin E2. Carboprost (15-methyl PGF_2-alpha) and methylergonovine can cause bronchospasm, so are contraindicated. Magnesium sulfate, which is a bronchodilator, is a safe choice for treating preterm labor. Indomethacin can induce bronchospasm in the aspirin-sensitive patient. There are no reports of the use of calcium channel blockers for tocolysis among women with asthma.

Lumbar epidural anesthesia has the benefit of reducing oxygen consumption and minute ventilation during labor.[43] Fentanyl may be a better analgesic than meperidine. Meperidine which causes histamine release is occasionally associated with the onset of bronchospasm during labor. Conduction analgesia is preferred since tracheal intubation can trigger bronchospasm.

Breastfeeding

Breast milk may contain very small amounts of the drugs used to treat asthma, but, in general, these are not known to be harmful to the infant. Prednisone, theophylline, antihistamines, beclomethasone, β_2-agonists and cromolyn are not considered as contraindications for breast feeding. However, among sensitive individuals, theophylline may cause toxic effects in the neonate, including vomiting, feeding difficulties, jitteriness and cardiac arrhythmias.

Pneumonia in Pregnancy

Pneumonia is the sixth leading cause of death overall and the number one cause of death from an infectious disease. Over 5 million cases occur annually, with more than 1 million persons requiring hospitalization.[44,45] Although associated with far less mortality, women of reproductive age are susceptible to pneumonia from a bacterial, viral or fungal source. Pregnant women do not get pneumonia more often than non-pregnant women, but can result in greater morbidity and mortality because of the physiologic alterations of pregnancy. These include a decrease in pulmonary functional residual capacity, as well as alterations in cell-mediated immunity. Thus, pregnant patients require a higher level of surveillance and intervention.

Currently, pneumonia has been classified into several types:[46] (1) Community-acquired pneumonia, commonly seen in young and pregnant women; (2) Healthcare–Associated Pneumonia (HCAP) resembles hospital acquired pneumonia; (3) Other types of pneumonia are nursing home acquired pneumonia and ventilator associated pneumonia. The hospitalization rate for community-acquired pneumonia in pregnant women was 1.51 per 1,000 pregnancies.[47] Several recent articles have reported an incidence of 1 per 660 deliveries.[47,48]

Hypoxemia and acidosis due to severe pneumonia are poorly tolerated by fetus and frequently stimulate preterm labor. Any pregnant women suspected of having pneumonia should undergo chest radiography.

Bacterial Pneumonia

Incidence and causes: Pregnancy causes no change in the course of pneumonia. Organisms found to cause bacterial pneumonia include *Streptococcus pneumoniae, Haemophilus influenzae, Chlamydia pneumoniae, Mycoplasma pneumoniae and Legionella pneumophila. Streptococcus pneumoniae* is the most commonly identified bacterial cause. Though in some studies causative organism could be identified in only 27% of cases, others identified the organism in 75% of patients.[49,50] Even with extensive diagnostic testing, the etiology may not be identified in 50% or more of cases.[51] A Gram's stain and culture of sputum can be helpful in focusing therapy, but its use is controversial. Bacterial cultures of sputum have poor sensitivity and specificity.[51] Risk factors for pneumonia include asthma and other chronic respiratory diseases, Human Immuno Deficiency Virus/Acquired Immuno Deficiency Syndrome (HIV/AIDS), smoking and drug use.[52]

Diagnosis: Signs and symptoms of bacterial pneumonia in pregnancy are same as in non-pregnant individuals: Cough (90%), sputum production (66%), dyspnea (66%) and pleuritic chest pain (50%).[53] In patients who have the findings of fever, crackles and abnormal breath sounds and in whom pneumonia is suspected, a chest radiograph should be performed. The chest radiograph will confirm pneumonia, rule out other diagnoses, suggest a possible etiology and aid in determining the severity of illness. Multilobar pneumonia is considered a more severe process than single lobar involvement (Table 165.4).[51]

TABLE 165.4: Criteria for severe community acquired pneumonia

- Respiratory rate $\geq$30/min
- $PaO_2/FiO_2 \leq 250$
- Multilobular infiltrates
- Confusion/disorientation
- Uremia
- Leucopenia – WBC <4,000/µl
- Thrombocytopenia – platelets <1,00,000/µl
- Hypothermia – temperature <36°C
- Hypotension requiring aggressive fluid resuscitation

Management: Generally, all pregnant women who have pneumonia are hospitalized for observation and initial therapy. Work-up should include a complete blood count, electrolytes, assessment of oxygenation and blood cultures; however, blood cultures have been found to be positive only 7 to 15% of the time.[52] Intravenous antibiotic therapy should be empirically started. Erythromycin is an acceptable initial choice for treatment, because it is considered safe in pregnancy. Treatment success rates up to 99% have been reported.[48] If gram-negative organisms or drug-resistant S pneumonia is suspected, a β-lactam, such as ceftriaxone or ampicillin should be added.

For women with severe disease, the American Thoracic Society guidelines call for: 1) fluoroquinolone – levofloxacin, moxifloxacin or gemifloxacin, 2) a β-lactam plus a macrolide. Most patients will have a clinical response within three days. Therapy should not be changed in the first 72 hours unless there is a marked clinical deterioration. Radiographic abnormality will take up to six weeks to resolve. Upto 20% of patients develop pleural effusion. Therapy is recommended for minimum of five days. [51]

Pregnancy outcome with pneumonia: Many different complications of bacterial pneumonia have been reported. Meningitis, arthritis, endocarditis, empyema and pericarditis have all been reported. Severe cases of pneumonia can be complicated by sepsis, heart failure, renal failure and Acute Respiratory Distress Syndrome (ARDS), requiring intensive care treatment.

Obstetric complications include fetal distress secondary to poor oxygenation and preterm birth. Women, who have pneumonia, are significantly more likely to deliver before 34 weeks.[54] Preterm birth has been reported to be more common when the woman who has pneumonia, has some underlying comorbid condition.[55] Anemia has also been reported in several studies of pneumonia during pregnancy.[48,52,54,56] Birth-weights of infants born to women having antepartum pneumonia have been found to be significantly less than the controls.[48,52]

Prevention: Pneumococcal vaccine is 60 to 70% protective. The vaccine is not recommended for otherwise healthy pregnant women. It is recommended for immunocompromised patients like those with HIV infection, diabetes, cardiac or renal disease and asplenia, such as sickle cell disease.[57]

Influenza

Influenza is a significant cause of morbidity and mortality from febrile respiratory illness worldwide. Influenza in pregnant women has historically been associated with a higher rate of morbidity and mortality.

High-risk groups include children aged 6 to 23 months; people aged 65 or older; residents of long-term care facilities, adults and children who have chronic illnesses, asthma, diabetes, immunosuppression and pregnant women. This risk is higher in pregnancy, if they have an underlying medical condition, are of advanced age or are exposed in the third trimester. In one study, women in the third trimester were three to four times more likely than postpartum women, to be hospitalized for an acute cardiopulmonary illness during influenza season.[58] Asthma in pregnant women increased the rate of hospitalizations for a respiratory illness during influenza season by 10-fold.[59]

Clinical presentation: The virus is spread from person to person via aerosolized droplets. Particles are created when a person coughs, sneezes or speaks. These particles are filtered in the recipient's nose and pharynx and then reach the alveoli.[60] The clinical presentation of influenza does not appear to be altered by pregnancy. The incubation period for influenza is one to four days, with an average of two days.[61] Patients are generally infectious the day before the onset of symptoms and for five days thereafter, however, young children and immunocompromised adults can shed virus for much longer periods of time.

Symptoms of influenza include cough, fever, malaise, rhinitis, myalgias, headache, chills and sore throat. Nausea and vomiting, otitis and conjunctival burning are less common symptoms. Signs of influenza include the presence of fever, tachycardia, facial flushing, clear nasal discharge and cervical adenopathy. Fever in adults generally lasts for three days, with resolution of symptoms normally within one week; however, the cough and malaise may persist for longer than two weeks.

Diagnosis: Influenza is usually diagnosed in the presence of clinical features during the influenza season. Rapid testing by either immunofluorescence or immunoassay has the advantage of providing same-day diagnosis; however, it does not have the same sensitivity as that of culture. Nasal samples provide a higher level of sensitivity than do throat samples when performing rapid testing. Patients who have a clinical picture are highly suggestive of influenza, but with a negative rapid test should still be cultured, because false negatives do occur.[60] Viral culture is necessary to subtype influenza, as well as for drug sensitivities.

Management: Supportive treatment with antipyretics and bed rest is recommended for uncomplicated cases. The antiviral agents' adamantanes, M2 ion-channel inhibitors, amantadine and rimantadine have activity only against influenza A. Given for chemoprophylaxis, they are 70 to 90% effective in preventing influenza. They also can be given within the first 48 hours of symptoms to reduce the symptom duration. The Center for Disease Control and Prevention in 2006 recommended against their use due to rapid resistance of influenza strain H3N2 to these drugs.[62]

The neuraminidase inhibitors are effective in the treatment of influenza A and B. Oseltamivir, given orally 75 mg twice daily, is approved for both treatment and chemoprophylaxis. It is reported to be 70 to 90% effective in preventing influenza.[63] The most commonly reported side effects are nausea and vomiting. Zanamivir is an inhaled medication approved only for treatment. It should be noted that there have been several reports of bronchospasm in patients of asthma after this drug.[64] Both shorten the duration of symptoms by, on an average, one day. There are limited data on their safety in pregnancy. All four are US FDA category C drugs and therefore should be used only when the benefits outweigh the risks.

Prevention/vaccination: The primary method of influenza prevention is vaccination. Vaccination is most effective when performed in October or November, although non-vaccinated patients should not be denied vaccination later in the season. The recommendation of the Advisory Committee on Immunization Practices (ACIP) is that all women who will be pregnant during the influenza season shall receive the vaccine. Vaccination can be performed safely in any trimester of pregnancy.[64] Breastfeeding is not a contraindication to vaccination. Of the two different vaccines available, the inactivated vaccine is used for pregnant women, as well as for all other high-risk groups.

Effects on pregnancy: Pneumonia, either viral or superimposed bacterial, is a well-recognized complication of influenza. Superimposed bacterial pneumonia typically occurs 2 to 14 days after the symptoms of influenza have resolved. Local consolidation is seen on chest radiograph with superimposed bacterial pneumonia. Myopathy is another complication that has been associated with influenza. Patients may develop rhabdomyolysis and myoglobinuria. In adults, myopathy is more commonly found with influenza A. Carditis has also been reported. Finally, encephalopathy is a rare complication of influenza. The virus has been isolated from Cerebrospinal Fluid (CSF) and brain tissue at autopsy.

Fetal effects: There is a paucity of prospective data on the effects of intrapartum, laboratory confirmed influenza on fetal outcome. There are no significant differences between women who had serum-confirmed influenza and controls, in the incidence of congenital malformations.[65] In the study of the influenza epidemics of 1957 to 1960, there was no increased incidence of fetal death or malformations in pregnant women who had influenza.[66] According to some studies, influenza has been associated with limb reduction and neural tube defects, including anencephaly.[67-69] Other investigators have not found an association between influenza and anencephaly. Some studies have noted an increased incidence of schizophrenia in people who were born two to three months after an influenza epidemic, implying that maternal exposure to influenza in the second trimester, when fetal neurons are migrating, is a risk factor.[70,71] There have also been reports of an increased incidence of cleft lip.[72]

Varicella Pneumonia

Varicella is a Deoxyribonucleic Acid (DNA) virus that affects 0.7 per 1,000 pregnancies.[73] Pneumonia is the most common complication in adults, occurring in 10% of cases.[74] The mortality rate in the era of antiviral therapy is approximately 14%. Risk factors for varicella pneumonia include smoking and the presence of 100 or more skin lesions.[75] Pulmonary symptoms cough, hemoptysis, dyspnea, tachypnea and pleuritic chest pain infiltrates begin 2 to 5 days after the onset of rash and fever. Treatment is with intravenous acyclovir, although its value has not been proven in rigorous scientific studies.[76]

Congenital varicella syndrome occurs in 1 to 2% of cases of maternal varicella, depending on gestational age.[76,77] In a study conducted by the Maternal Fetal Medicine Units Network, the rate of congenital varicella was 0.4% in 347 pregnant women who had varicella.[78] Congenital varicella is characterized by limb hypoplasia, chorioretinitis, cutaneous scars and cortical atrophy.[79,80] Varicella pneumonia has been also associated with preterm labor.[79] Varicella-zoster immunoglobulin given within 96 hours of exposure to varicella can attenuate or prevent infection in susceptible individuals. It is not contraindicated in pregnancy. The varicella vaccine, however, is contraindicated in pregnancy because it is a live-attenuated vaccine.[81]

Severe Acute Respiratory Syndrome

Severe Acute Respiratory Syndrome (SARS) is caused by a novel coronavirus. Since 2002, this atypical pneumonia has affected over 8,000 people and resulted in more than 800 deaths worldwide.[82] Transmission is by respiratory droplets or close personal contact. The virus can live in urine and stool for 1 to 2 days. Symptoms are the same in pregnant as in non-pregnant women. Various symptoms include fever, chills, rigors, malaise and myalgias.[83]

Complications of SARS pneumonia include respiratory failure, superimposed bacterial infections and Disseminated Intravascular Coagulation (DIC). The largest case series of pregnant women who had SARS reported high rates of morbidity and mortality.[84] The case fatality rate was 25%. A large portion of the cases was complicated by first-trimester spontaneous abortions, preterm births and intrauterine growth restriction; however, there have been no cases of vertical transmission reported. Treatment includes broad-spectrum antibiotics to cover superimposed bacterial infections, high dose steroids and possibly ribavirin. Ribavirin has been shown to have teratogenic effects in animals; its use in pregnancy has not been established.

Fungal Pneumonia

Fungal pneumonias with *Aspergillus, Candida* and *Cryptococcus* are seen in those women who are immunocompromised or hospitalized.[85] Management of these opportunistic fungal infections during pregnancy is same as in non-pregnant women. These are generally serious, life-threatening conditions. With the physiologic suppression of cell-mediated immunity in pregnancy, endemic fungal pneumonias can be seen in otherwise healthy women. There have only been a handful of cases of pneumonia secondary to histoplasmosis.[86] Of 19 cases of blastomycosis in pregnancy, 78% had pulmonary involvement; all recovered or were at least reported as having a "good response."[87]

The 2007 American Thoracic Society Guidelines recommend the use of itraconazole in disseminated fungal infections.[88] However, this may be embryotoxic in large doses, so avoided in early trimester. Regardless of the type of pneumonia, it is important to be aggressive with monitoring and treatment for the sake of the mother and the fetus. Broad-spectrum empiric antibiotics should be started before the identification of the etiologic agent, antibiotic therapy should be tailored to specific organisms. Given that the majority of pregnant women are young and healthy, intense, early treatment is likely to result in a good outcome.

With the increasing number of pregnant women infected with HIV, *Pneumocystis jiroveci* pneumonia (PJP), previously known as *Pneumocystis carinii* is a common complication. Among pregnant women, this is a leading cause of AIDS-related death in the United States.[89] Symptoms include dry cough, dyspnea and tachypnea. A diffuse infiltrate is seen on chest radiograph.

In a report of 22 cases of PCP in pregnancy, the mortality rate was extremely high at 50%, while 59% required mechanical ventilation.[90] These numbers may be inflated since none of the patients had received antiretroviral therapy, all were diagnosed with HIV when diagnosed with PJP. Treatment is given with trimethoprim-sulfamethoxazole or pentamidine. HIV-infected patients who have a $CD4^+$ T-lymphocyte count of less than 200/mL, a history of oropharyngeal candidiasis, or an AIDS-defining illness should receive prophylaxis.[91] The preferred regimen is trimethoprim-sulfamethoxazole, one double-strength tablet per day. Prophylaxis is 90 to 95% effective.

Tuberculosis and Pregnancy

Considering the high prevalence of Tuberculosis (TB) in India, a large number of pregnant women can be expected to suffer from TB, but exact data about the proportion of pregnant women with tuberculosis are unavailable. The clinical and laboratory diagnosis and treatment during pregnancy, safety of anti-tuberculosis therapy and excretion of these drugs in breast feed are concerns of the physicians giving care to these pregnant women. The diagnosis and management of tuberculosis in pregnancy is of utmost importance, especially since the untreated disease poses much greater risk to both the mother and the fetus.

Clinical Presentation

About half to two-thirds of pregnant women with tuberculosis remain asymptomatic.[92] The clinical presentation of tuberculosis in the pregnant women is similar to that in the non-pregnant patients (Table 165.5). Non-specific symptoms like lethargy, alteration in bowel habit, or failure to gain weight are commonly interpreted as usual symptoms of pregnancy, hence the cause of delay in the diagnosis.[93]

TABLE 165.5: Symptoms of tuberculosis in pregnancy

Common	*Less common*
Cough, sputum	Lethargy, malaise
Weakness, weight loss	Abdominal distension
Fever, sweating	Irritability, headache
Hemoptysis	Skin lesions, lymph nodes
Fatigue, tiredness	Alteration in bowel habit

During pregnancy, pulmonary tuberculosis is more common than extrapulmonary tuberculosis. Only 5 to 10% of pregnant women have extrapulmonary disease most commonly of lymph nodes, pleura, genitourinary tract, bones, joints, meninges and peritoneum.[92-95] Extrapulmonary tuberculosis is now seen more often because of HIV coinfection.

Effect of Pregnancy on Tuberculosis

Effect of pregnancy on tuberculosis was a matter of controversy since the days of Hippocrates.[96] Raised diaphragm during pregnancy was believed to cause atelectasis of basal lung regions.[97] In early 20th century, it was believed that pregnancy has deleterious effects on tuberculosis and induction of abortion was recommended.[94,98] Now, it is believed that TB gets flared up by the stress of pregnancy, especially if associated with poor nutritional and immunodeficient states, or coexistent diseases. There is also an increased risk of development of postpartal TB during lactation, due to the loss of protective antibodies in mother.[99] However, all this is still controversial and more studies are needed to support these hypothesis.

Effect of Tuberculosis on Pregnancy (Table 165.6)

The pulmonary and extrapulmonary forms of tuberculosis affect pregnancy in the same way as in non-pregnant state (Table 165.7).[100-104] With the advent of chemotherapy, most studies have demonstrated that TB does not increase complications of pregnancy and labor.[94]

TABLE 165.6: Effects of tuberculosis on pregnancy

- Spontaneous abortions
- Intrauterine death
- Premature labor
- Small for gestational age neonates
- Low birth-weight
- Increased perinatal mortality

Diagnosis

It is important to identify pregnant women with tuberculosis since an early diagnosis and treatment will result in better maternal and neonatal outcomes. A careful history is mandatory in high-risk cases in the antenatal period. History of exposure to tuberculosis and the similarities of symptoms between tuberculosis and pregnancy should be kept in mind.

Chest radiograph: In the past, chest X-ray was advocated to detect tuberculosis. In view of the risk of radiation

TABLE 165.7: Studies showing effect of tuberculosis on pregnancy

	Study	*Year*	*Outcome*
1.	Selikoff et al[100]	1965	Seven spontaneous abortions, nine antepartum and intrapartum fetal deaths
2.	Schaeffer et al[101]	1975	No increased risk of prematurity
3.	Jana et al[102]	1994	Two fold increase in prematurity, small for gestational age and low birth-weight neonates, 6-fold increase in perinatal deaths
4.	Maurya and Sapre[103]	1996	Four spontaneous abortions, two premature delivery, one intrauterine death
5.	Kothari et al[104]	2006	Two abortions, two preterm deliveries

exposure, the routine use of chest radiograph is not justified. If tuberculin skin test is greater than 10 mm of induration, a chest radiograph should be obtained in asymptomatic patient with proper abdominal shielding preferably after first trimester.

Tuberculin skin test: In India where about half of the population is tuberculin positive, the routine use of the test remains questionable. Tuberculin test is deemed a safe and useful method for screening tuberculosis infection in pregnancy (Table 165.8).

TABLE 165.8: Indications of tuberculin skin test during pregnancy

- Symptoms and signs of tuberculosis
- Pregnant women with diabetes or HIV
- Women employed in hospitals, old age homes
- Prisoners
- Low socioeconomic status

In women who are HIV positive, there may be diminished or negative tuberculin reaction, therefore an area of 5 mm or greater induration in an HIV-positive patient is considered positive.[105]

Microbiological methods: Essential laboratory methods for detection or verification of infection include microscopy, culture, nucleic acid amplification assays and drug susceptibility testing. Demonstration of Mycobacterium tuberculosis by Ziehl-Neelsen staining or culture in sputum or material obtained confirms the diagnosis. Bronchoscopy may be required if patient is unable to produce sputum.

Treatment of Tuberculosis in Pregnant Women

Treatment with Anti-Tuberculosis Treatment (ATT) should be initiated without delay when TB is diagnosed in pregnant women. The decision to treat tuberculosis in pregnancy must keep into account the potential benefits and risks to mother and fetus. It is widely considered that the benefits of treating tuberculosis in pregnancy outweigh any risk of treatment. The indications for treatment of active tuberculosis in pregnant women are the same as for non-pregnant women. None of the first line ATT, isoniazid, rifampicin, streptomycin and ethambutol (Table 165.9) was found to be teratogenic, except streptomycin which caused ototoxicity in fetus.

TABLE 165.9: First line anti-TB drugs used in pregnancy

Anti-TB drug	*Mode of action*	*Recommended dose (mg/kg)*
Isoniazid (H)	bactericidal	5 (4–6)
Rifampicin (R)	bactericidal	10 (8–12)
Ethambutol (E)	bacteriostatic	15 (15–20)
Pyrazinamide (Z)	bactericidal	25 (20–30)

The same regimens are recommended for use in pregnancy as for the non-pregnant state with the exception of streptomycin. Pyrazinamide should preferably be avoided in pregnancy. Currently, an intermittent regimen (thrice weekly on alternate days) under the Directly Obeserved Treatment Short-Course (DOTS) strategy of Revised National Tuberculosis Control Program (RNTCP) is increasingly used worldwide for the pregnant women having tuberculosis.[106] In a retrospective analysis of 12,367 TB patients who were put on DOTS, there were 16 pregnant women suffering from either pulmonary or extrapulmonary form of disease, of whom 25% had become pregnant while receiving ATT; all the 16 completed their treatment without any adverse pregnancy outcome.[107]

Treatment of Tuberculosis in Lactating Women

The safety of breastfeeding, if mother is on ATT, is a very important issue. There is general consensus that although small concentrations of anti-tuberculosis drugs are excreted in breast milk, treatment for tuberculosis is not a contraindication to breastfeeding. Under RNTCP, breastfeeding of neonates is recommended regardless of the mother's tuberculosis status.

Care of newborn:

- If the mother is sputum-positive or on ATT, the infant needs evaluation for active tuberculosis with chest

radiograph and examination of gastric aspirate or sputum for Acid Fast Bacilli (AFB).
- If there is no evidence of active tuberculosis, the infant should receive INH prophylaxis for three months or until after the mother's sputum becomes negative and the baby is tuberculin negative.
- Bacillus of Calmette and Guerin (BCG) vaccination may be postponed or done with INH-resistant BCG vaccine.
- If the infant is tuberculin positive, the INH prophylaxis should be given for a total period of six months after ruling out active tuberculosis.
- If the mother is suffering from Multi Drug-Resistant Tubercle Bacilli (MDR–TB), then INH prophylaxis has no role, hence should not be given. In such cases, the infant should receive BCG vaccination, which has been shown to have a protective effect.[108-110]
- BCG is contraindicated in HIV-positive children.

If tuberculosis is diagnosed and treated appropriately and early, the prognosis for both mother and child is excellent.

Contraception: Rifampicin accelerates the metabolism of oral contraceptives and other drugs resulting in sub-therapeutic serum levels.[94] So, the reliability of oral contraceptive is decreased in women taking ATT.[111] All other contraceptive measures can be considered in postpartum women taking anti-tuberculosis treatment.

Pulmonary Embolism

Peripartum hemorrhage (PE) is the leading cause of maternal mortality in the developing world, whereas it is Venous Thromboembolism (VTE) in the developed nations.[112] The incidence of VTE in pregnant women, derived from retrospective cohort studies, is estimated as 5–12 events per 10,000 pregnancies antenatally (from conception to delivery), seven to ten times higher than the incidence in age-matched controls. The risk is similar in all three trimesters.[114]

Signs and symptoms of Pulmonary Embolism (PE) are not diagnostic because dyspnea and tachypnea are common in pregnancy. In non-pregnant patients, tachypnea, dyspnea, chest pain (pleuritic), apprehension and crackles are present in atleast 50% of patients. Chest radiographs are abnormal in 80% or more of patients. Electrocardiogram findings are abnormal, but nonspecific in 70% of patients with PE. Arterial oxygen tension is low in the majority of patients with PE.[115]

Objective Diagnostic Testing

As with VTE, PE requires objective diagnostic testing to confidently confirm or exclude the diagnosis. This is particularly true in pregnancy. The diagnosis of VTE or PE necessitates: (1) prolonged therapy (2) prophylaxis during future pregnancies, and (3) avoidance of oral contraceptive pills.

The first objective diagnostic test should be compression ultrasonography. Perfusion scanning alone is recommended initially, the ventilation scan is added when perfusion defects are noted. Pulmonary angiography is necessary if lung scan findings are of low probability or are indeterminate and the clinical suspicion remains high. Several studies show no increased risk of teratogenicity in patients undergoing radiological procedures in the diagnosis of maternal venous thromboembolic disease. A complete and adequate evaluation to document the presence or absence of PE requires a dose of less than 0.005 gray of the radioisotope.[116]

Management

Patients, whether pregnant or not, in whom PE is strongly considered should be treated immediately with intravenous unfractionated heparin unless a high risk or contraindication is present for the use of any anticoagulant. Extensive clinical experience and cohort studies establish heparin as the safest anticoagulant to use during pregnancy, because it does not cross the placenta. The initial loading dose of 5,000–10,000 units is followed with an infusion of 18 U/kg. The patient's activated partial thromboplastin time should be monitored and kept in the therapeutic range of 1.5–2 times the baseline value.

Low Molecular Weight Heparin (LMWH) is the treatment of choice for PE in pregnant (and non-pregnant) patients. LMWH is atleast as effective and safe as Unfractioned Heparin (UFH) in non-pregnant women for the treatment of acute VTE.[117,118] Although only a relatively modest amount of data have been gathered, low molecular weight heparin, which does not cross the placenta, can be given once a day and does not require monitoring. Low molecular weight heparin has not been shown to increase the risk of bleeding with surgical procedures, including with the cesarean delivery.[119]

Warfarin should be avoided throughout pregnancy. It can result in embryopathy characterized by mental retardation, optic atrophy, cleft lip, cleft palate and cataracts in addition to hemorrhage. The teratogenic effects are particularly common during the first trimester. Warfarin crosses the placenta; it can cause fetal and neonatal hemorrhage and placental abruption.[120]

Patients who sustain a VTE or PE antepartum should receive anticoagulation therapy with heparin throughout the pregnancy. After delivery, warfarin should be started; the heparin can be discontinued once an adequate International Normalized Ratio is achieved. Warfarin should be continued for atleast six weeks postpartum or until atleast three months of anticoagulant therapy have been completed.

Complications of Treatment

Osteopenia has been reported with unfractionated heparin administered for more than six months. No information is available about the beneficial effects of concomitant multivitamins, calcium or vitamin D supplementation. The problem of osteopenia and osteoporosis might be less with low molecular weight heparin, but providing optimum calcium and vitamin D supplementation is reasonable for all patients receiving long-term heparin administration during pregnancy.

Prophylaxis

In women with history of VTE during pregnancy, the recurrence rate in a subsequent pregnancy has been estimated as 4 to 15%. Women with a known hypercoagulable state are also at increased risk of VTE during pregnancy and should receive prophylaxis. Effective prophylaxis has been demonstrated with unfractionated heparin administered twice daily with an average daily dose of 16,400 IU/d or 225 IU/kg of body weight per 24 hours. The amount of heparin required for adequate prophylaxis might increase through the second and third trimester. Therefore, heparin should be adjusted to mid interval plasma heparin levels of 0.05–0.25 U/mL measured as factor Xa activity. Low molecular weight heparin is most appropriate for prophylaxis because it requires a single daily dose, does not require laboratory monitoring and may be associated with a lower risk of osteoporosis and bleeding.

Sarcoidosis

A large number of restrictive, Interstitial Lung Diseases (ILD) affect women, including in the child-bearing age. Of them, sarcoidosis is particularly important and frequently recognized in India.[121] Sarcoidosis, is a multisystem granulomatous inflammatory disease, commonly seen in female.[122] Clinical presentation may vary in different individuals, more than half of the patients have dyspnea and dry cough with or without constitutional symptoms and around 10 to 20% of patients are asymptomatic at the time of diagnosis.[120]

There is no evidence that sarcoidosis affects fertility. Although the reproductive organs may be pathologically involved, there is no evidence to support any link between the disease and decreased fertility in women. Many investigators have evaluated the effect of pregnancy on the course of sarcoidosis.[123] Sarcoidosis generally does not prevent successful pregnancy and delivery, the endogenous estrogen in pregnancy may even have a slightly beneficial immunomodulatory effect. In most cases, the course of sarcoidosis is unaffected by pregnancy, there is improvement in a few cases and worsening of symptoms in very few cases.[124]

Pregnancy may represent a significant stress in patients with severe, pre-existing physiologic derangements caused by sarcoidosis. Individuals with a normal chest radiograph before pregnancy generally remain stable during pregnancy and in the postpartum period. The presence of parenchymal lesions on chest radiograph, advanced radiographic stage and extrapulmonary disease have been suggested as prognostic markers for progression of disease during pregnancy.[125]

Indications for treatment in pregnant patients are same as in non-pregnant patients, including patients with progressive pulmonary disease and vital organ involvement.[123,126] Anticipatory observation for difficulties with early augmentation or initiation of therapy is warranted throughout the pregnancy. If symptoms secondary to sarcoidosis develop or increase and require corticosteroid therapy, the patient should be monitored carefully for glucose intolerance and infectious complications. Management of labor and delivery should be directed by obstetric indications, with general goals directed to minimize pain and decrease oxygen consumption.[127]

Good maternal and fetal outcomes are possible in women with restrictive lung disease in general and with sarcoidosis in particular. The management of pregnancy, labor and delivery are not altered by the presence of sarcoidosis. After delivery, all patients with sarcoidosis should be evaluated routinely for a possible relapse of disease.

Cystic Fibrosis

Cystic Fibrosis (CF) is an autosomal disorder arising from a defect on chromosome 7 in the region coding for the CF transmembrane regulator protein. Disordered production or function of this protein results in abnormal chloride transport and sodium and water movement across glands in many organ systems. The resulting desiccated, tenacious secretions lead to loss of function and eventual organ damage. The clinical picture is dominated by early bacterial colonization of the airways and chronic airway infection, leading to bronchiectasis and obstructive pulmonary disease. The decline in lung function is inevitable and eventual respiratory failure causes death in more than 90% of patients with CF.[128]

Better understanding of the pathophysiology of CF and aggressive treatment with antibiotics, mucolytics and airway clearance techniques and attention to nutritional parameters resulted in dramatically prolonged survival. The median survival increased from less than 1 year in the 1940s to an estimated 40 years in 2002.

Infertility

It is commonly believed that women with CF have fertility problems secondary to multiple causes, including malnutrition-induced delayed menarche and ovulation, cervical plugs caused by thickened secretions, and frequent vulvovaginal infections.[128] A Scandinavian study showed that 75% of women with CF succeeded in becoming pregnant.[129] Pregnancy is possible in patients with CF; even patients who are underweight or require transplantation, can conceive.

Pregnancy and Cystic Fibrosis

Early reports of pregnancy in patients with CF were discouraging, but attested to the safety of pregnancy in women with good lung function.[130-132] Pregnant women with severe pulmonary dysfunction had shorter gestation periods and increased perinatal mortality rates than did pregnant women with preserved lung function.[131]

Other investigators also concluded that pregnancy had little impact on patients with mild disease, but resulted in poor outcome for those with advanced disease, leading some researchers to suggest that pregnancy can be terminated in women with CF in whom the forced vital capacity or forced expiratory volume in 1 second (FEV_1) is 50 or 60% of predicted or less, respectively.[132,133] However, there are a number of reports of women with CF and severely diminished spirometry who gave birth without complications.[133] Other factors that may affect long-term survival are nutritional status, the existence of diabetes mellitus, the presence of Burkholderia cepacia and frequent infectious exacerbations. The Cystic Fibrosis Foundation (CFF) National Patient Registry database Information from the registry showed no difference in the rate of hospital admissions, use of home intravenous antibiotics, use of supplemental oxygen and supplemental feedings in the year after pregnancy.[134] Most investigators agree that pulmonary hypertension, a late complicating event, is likely an indication for counseling against pregnancy or for therapeutic abortion.[128-130]

Management

Preconception genetic counseling of both future parents should be offered. Women with cor pulmonale and pulmonary hypertension should be counseled against pregnancy. Women can be advised that there is little evidence that the child will be affected by the mother's CF or by medication used to treat exacerbation through the course of pregnancy. Women who choose to become pregnant should have close surveillance for the development of superimposed infection, diabetes and heart failure. The ability of the mother to carry a pregnancy to term seems to relate to lung function before pregnancy. They should be monitored closely with pulmonary function tests. When the FEV_1 is generally at least 70%, pregnancy is tolerated well. β-adrenergic bronchodilators for bronchoconstriction, inhaled recombinant human deoxyribonuclease to reduce sputum viscosity are used in managing these patients. Pancreatic insufficiency is treated with the replacement of oral pancreatic enzyme. Appropriate dietary counseling is also given to these patients. Pulmonary infections are treated with appropriate antibiotics and threshold for hospitalization is low. For labor and delivery, epidural analgesia is recommended.

Pregnancy-Specific Problems

Besides the lung diseases which complicate pregnancy, there are several pregnancy specific problems (Table 165.10), which may frequently pose problems of diagnosis and treatment.

TABLE 165.10: Some important pregnancy-specific pulmonary problems

- Amniotic fluid embolism
- Tocolytic pulmonary edema
- Pre-eclampsia and pulmonary edema
- Peripartum cardiomyopathy
- Gestation

Amniotic Fluid Embolism[135]

Amniotic fluid embolism is a rare (1 case per 8,000–80,000 births), but potentially catastrophic complication, with a mortality rate of 10 to 80%. This usually occurs with labor and delivery, but can be associated with uterine manipulation, uterine trauma and the early postpartum period. Amniotic fluid containing particulate cellular elements enters the vascular circulation through endocervical veins or uterine tears, obstructs the pulmonary vessels and causes vascular spasms, resulting in pulmonary hypertension. Acute left ventricular failure might occur, probably due to humoral events mediated by cytokines.

Clinical presentation usually involves a sudden onset of severe dyspnea, hypoxemia and cardiovascular collapse. Hemorrhage caused by disseminated intravascular coagulation and fetal distress are other less common presentations. The diagnosis of amniotic fluid embolism is usually based on the typical clinical picture. Fetal squamous cells in a wedged pulmonary capillary aspirate have been used to confirm the diagnosis, but are not specific. The differential diagnoses include septic shock, pulmonary thromboembolism, ruptured placentae, tension pneumothorax and myocardial ischemia.

Treatment involves routine resuscitative and supportive measures with prompt attention to adequate oxygenation, ventilation and inotropic support. No specific therapy has been shown to be effective, although corticosteroids have been suggested. The survivors may develop complications of disseminated intravascular coagulation, ARDS, or both.

Tocolytic Pulmonary Edema[136]

β-adrenergic agonists, particularly ritodrine and terbutaline, are used to inhibit uterine contractions and preterm labor. These might cause pulmonary edema during pregnancy. The frequency varies from 0.3 to 9%. Mechanisms include prolonged exposure to catecholamines (which causes myocardial dysfunction), increased capillary permeability and a large volume of intravenous fluid that may have been administered in response to maternal tachycardia. Glucocorticoids administered in preterm labor can also contribute to fluid retention. The clinical presentation is that of acute respiratory distress with the features of pulmonary edema. The diagnosis is generally made in an appropriate clinical situation. The differential diagnoses include cardiogenic pulmonary edema, amniotic fluid embolism and aspiration pneumonia β-agonist therapy must be discontinued; pulmonary edema usually resolves rapidly. The additional treatment which includes diuresis is mostly supportive.

Pre-eclampsia and Pulmonary Edema[137]

Pulmonary edema may rarely occur in association with preeclampsia (approximately 3%). Patients with preeclampsia are usually volume depleted, pulmonary edema most commonly occurs in the early postpartum period, often associated with aggressive fluid replacement. Reduced albumin concentration and myocardial dysfunction contribute to edema formation. The presentation is of an acute respiratory distress in a patient with preeclampsia. The standard approach is to restrict fluids, administer supplemental oxygen and diuresis. Invasive monitoring might be useful if inotropic vasodilator therapy becomes necessary.

Peri-partum Cardiomyopathy

Cardiogenic pulmonary edema is an important consideration in the differential diagnosis of acute respiratory failure in pregnancy. Cardiac failure can occur in the absence of preexisting heart disease as a result of hypertensive disease of pregnancy and peripartum cardiomyopathy. This idiopathic condition presents during the last month of pregnancy or during the postpartum period and is associated with significant mortality. During labor and early postpartum, tachycardia and increased cardiac output can precipitate pulmonary edema.

Gestational Trophoblastic Disease

Pulmonary hypertension and pulmonary edema can complicate benign hydatidiform pregnancy due to trophoblastic PE. This commonly occurs during the evacuation of the uterus, the incidence of pulmonary complications is higher in later gestations. Molar pregnancy can also be associated with the development of choriocarcinoma, which commonly produces multiple discrete pulmonary metastases and occasional pleural effusions.

Rare Lung Diseases

Sanjeev Mehta, PS Shankar

PART I: PULMONARY ALVEOLAR PHOSPHOLIPOPROTEINOSIS

Sanjeev Mehta

INTRODUCTION

Pulmonary Alveolar Proteinosis (PAP) is a rare, idiopathic and diffuse lung disease, characterized by the accumulation of large amounts of surfactant within the alveolar spaces. The name pulmonary alveolar proteinosis, as it is commonly known, is actually a misnomer, since only 2% of the intra-alveolar content is protein, the rest is mostly dipalmitoyl lecithin. Hence, pulmonary alveolar phospholipoproteinosis is more appropriate term for this condition.

Initially, described by Rosen et al. in 1958, PAP is characterized by pulmonary infiltrates with varying degrees of hypoxemia.[1] The disease is rare, with an estimated prevalence of only 0.37 per 100,000 people and an incidence rate of one in two million people. Male:female ratio is 3:1. 72% patients have a history of smoking and that may account for some of the male predominance. Over 80% of cases, occur in the third or fourth decade of life, with a median age of diagnosis of 39 years.[2]

Etiology and Pathophysiology

Pulmonary Alveolar Proteinosis is likely a common phenotypic response to a number of biochemical or molecular abnormalities, resulting in altered surfactant homeostasis, i.e. excessive production and/or reduced clearance of surfactant, by defective function of the alveolar macrophage and the growth factor necessary for its maturation, the Granulocyte Macrophage-Colony Stimulating Factor (GM-CSF). There is recent evidence to suggest a strong association of autoantibodies to GM-CSF or GM-CSF receptor gene mutations, which has implicated GM-CSF, signalling abnormalities in the pathogenesis of PAP. Thus, deficiency in GM-CSF activity may be responsible for PAP and opens the possibility of its treatment with GM-CSF augmentation therapy.

Clinical Classification

Multiple clinical forms of PAP have been described based on presumed etiology.[3,4] Most cases are idiopathic or primary PAP. These are likely caused by mutations in the genes encoding surfactant protein B or C or the C chain of the receptor for GM-CSF. While, the exact etiology is unknown, most patients are smokers. Secondary pulmonary alveolar proteinosis develops in association with conditions involving functional impairment or reduced numbers of alveolar macrophages. These are being increasingly recognized and PAP like pathology is noted in several conditions, as mentioned in Table 166.1.

Pathology

Under light microscopy, the alveoli and terminal bronchioles are filled with an eosinophilic, granular lipoproteinaceous material that stains deep pink with Periodic Acid Schiff (PAS) stain. This fluid consists of phospholipids and surfactant proteins A, B, C, and D and tubular myelin, membranous vesicles and structures that on electron microscopy are recognized, as lamellar bodies. These lamellar bodies are phospholipids that are

TABLE 166.1: Causes of secondary pulmonary alveolar proteinosis

- Subjects exposed to volcanic ash, aluminum dust, titanium, chlorambucil and busulfan
- Conditions, where alveolar macrophage function may be altered or suppressed
  - Immunodeficiency states
  - Hematological malignancies, e.g. myeloid leukemias, neutropenia and lymphomas
  - Fanconi’s anemia
  - IgG monoclonal gammopathy
  - Silico-proteinosis (in sandblasters)
  - Atypical mycobacterioses
  - Pneumocystis carinii pneumonia
  - Mycoses
- Pulmonary diseases associated with/aggravated by smoking:
  - Chronic Obstructive Pulmonary Disease (COPD)
  - Interstitial Pulmonary Fibrosis (IPF)
  - Carcinoma
  - Calcification of pleural plaques in asbestosis
  - pulmonary eosinophilic granuloma
  - Alveolar hemorrhage in Goodpasture syndrome

identical to inclusions found in normal type II pneumocytes. The cellular component of PAP in the Bronchoalveolar Lavage (BAL) fluid consists predominantly of enlarged, foamy macrophages, which contain numerous complex phospholipoprotein inclusions. The alveolar architecture is well-preserved in “primary” form of PAP, this is shown in Figure 166.1. In secondary PAP, septal thickening, edema and lymphocytic and neutrophilic infiltration can be seen, as illustrated in Figure 166.2.

Symptoms and Signs

1. PAP has been noted in young and middle aged individuals
2. Males are often more affected than females
3. It involves the lungs alone
4. Clinically, nearly one-third are asymptomatic or minimally symptomatic.[3,4] Most patients with acquired PAP, present with progressive exertional dyspnea of insidious onset and cough. Less frequently fever, chest pain or hemoptysis occurs, especially if secondary infection is present.
5. In some patients, PAP may begin with an initial febrile episode, followed later by progressive dyspnea, productive cough, low grade fever, chest pain and loss of weight. Cough is minimally productive with gelatinous white “chunky” expectoration. Hemoptysis is rare.

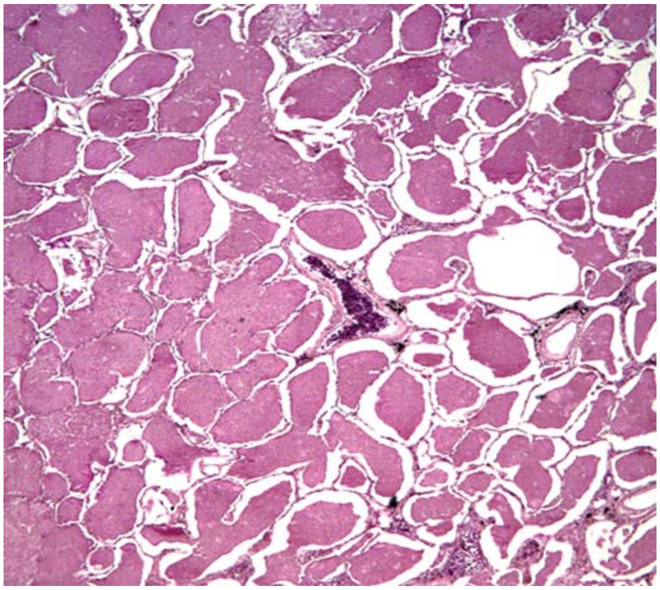

Fig. 166.1: Alveolar eosinophilic material filling the alveolar lumina with preserved architecture in primary alveolar proteinosis

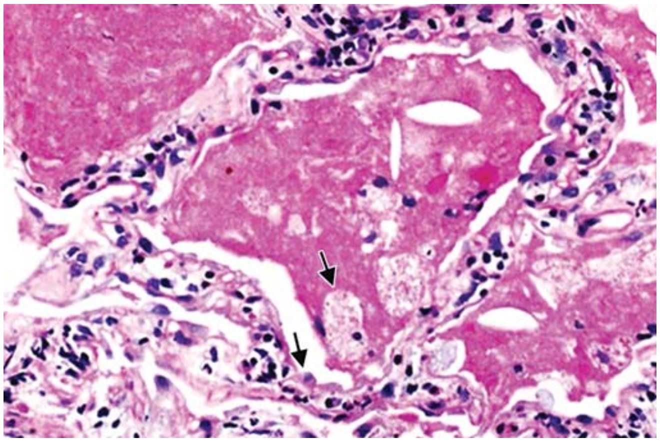

Fig. 166.2: Secondary PAP: Septal thickening, edema and inflammatory infiltration of alveoli

6. Physical examination may be unremarkable, but crackles are present in about 50%, cyanosis in 25% and clubbing in a smaller number of patients.

Radiology

The extent of radiographic abnormalities is often disproportionate, to the severity of the symptoms and physical findings. The chest X-ray shown in Figure 166.3, usually reveals bilateral air space infiltrates with an ill-defined acinar nodules, ground glass opacification or confluent pattern, greater in the lower two-thirds of the lungs. It may be asymmetric in 20%. The “classic” perihilar

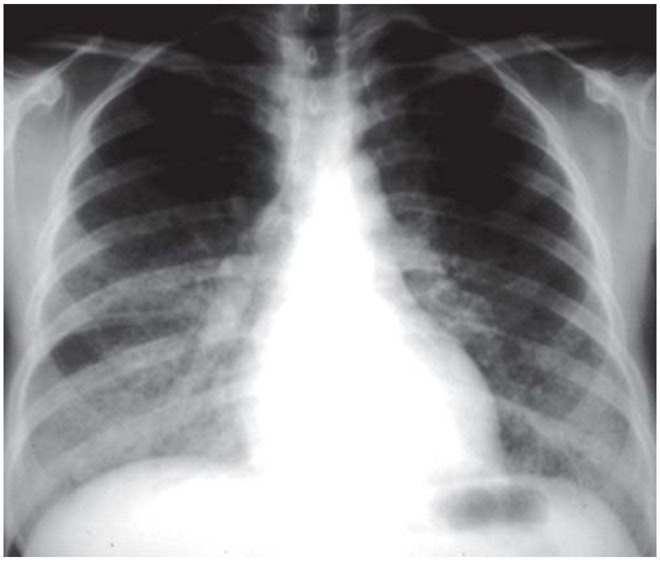

Fig. 166.3: Chest roentgenograph of PAP-bilateral air space infiltrates, acinar nodules and ground-glass opacification

"bat wing" or "reverse pulmonary edema" pattern is seen in about 50% cases. Air bronchograms are not a predominant feature of this disease. As the disease progresses, the alveolar infiltrates become denser. High Resolution Computed Tomography (HRCT) scan of the chest, shown in Figures 166.4A and B reflects the alveolar filling process, as patchy airspace consolidation (ground glass opacity) with thickened interlobular septae, which are predominantly perihilar, with relative sparing of the peripheral lung. Accentuation of the interlobular septa is usually caused by presence of the proteinaceous material in the septal interstitium. There is a sharp transition between the normal and the abnormal lung. It is described as "crazy paving" an appearance that is characteristic, but not entirely specific for PAP. In chronic cases, interstitial infiltration (early fibrosis) can be seen.

Laboratory Tests

Routine laboratory tests are usually unremarkable. There may be mild leukocytosis. Elevated serum Lactate Dehydrogenase (LDH) may be a useful marker. Elevated serum levels of carcinoembryonic antigen, cytokeratin 19, mucin KL-6 and surfactant proteins A, B and D have been reported, but of unclear value.

Pulmonary function tests usually reveal a restrictive ventilatory defect, with reduced lung volumes and a disproportionate reduction in Diffusing Capacity of Carbon Monoxide (DLCO). Hypoxemia caused by ventilation-perfusion inequality and intrapulmonary shunting is common, resulting in a widened alveolar-arteriolar diffusion gradient. Open lung biopsy has been the gold standard for diagnosis, but bronchoscopic lung biopsy may suffice. Bronchoalveolar lavage is also helpful. Aspiration of opaque milky or sandy or light-brown fluid from an affected segment is characteristic. BAL material stains pink with PAS, but negative with alcan blue, which allows the differentiation of the phospholipoprotein aggregates from mucins. Assay using monoclonal antibodies to SF-A has shown Surfactant Protien-A (SP-A) concentrations are 400 times higher in patients with PAP than in controls. It appears to be useful for diagnosis of PAP, especially where lung biopsy is contraindicated. Serum lactic acid dehydrogenase may be elevated.

Treatment

Therapy is essentially supportive. About 30% patients may improve spontaneously, especially those with a $PaO_2 \geq 70$ mm Hg) or P Alveolar-arterial (A-a) $O_2 \leq 40$ mm Hg. Steroids have not shown to be beneficial.

Treatment of the underlying cause should be undertaken, wherever possible. Aggressive attempts should be made at cessation of smoking.

Whole lung lavage, using normal saline, one lung at a time is the mainstay of therapy.[5,6] The usual reported benefit is for 15 months. Patients with severe and or recurrent disease require repeated lavages at intervals of several weeks to months. When whole lung lavage can not be performed, segmental or lobar lavage, using flexible bronchoscope can be attempted. Whole lung lavage is not having any effect on the pathogenetic mechanisms and is often associated with many complications. Subcutaneous and inhaled administration of GM-CSF has been reported to be effective, but this strategy, while promising, remains experimental. Aerosolized trypsin has been used to treat PAP, but the results are not consistent. Treatment of infection and supportive care, such as the use of oxygen should be administered as appropriate. Lung transplantation is rarely indicated for an advanced disease.

Progress and Complications

Progressive respiratory failure occurs from disease persistence. Interstitial fibrosis develops in chronic cases. Infection with unusual organisms, such as *Nocardia* species, *Aspergillus* species, *Mycobacteria*, *Pneumocystis*, *Cryptococcus* neoformans and other organisms are known to occur.

PART II: PULMONARY CALCIFICATION AND OSSIFICATION SYNDROMES

Sanjeev Mehta

Pulmonary calcification is commonly seen on the chest X-ray and is usually an incidental finding. It may be metastatic, benign or malignant or dystrophic in origin. The list of causes is rather exhaustive.[1] Frequency-wise, the dystrophic causes of infectious etiology are more common, as shown in the Table 166.2.

The condition depends on abnormalities in serum calcium and phosphate concentration, alkaline phosphatase activity and local physicochemical conditions, such as pH. It is most common after about 10 years of hemodialysis.

Pathophysiology

Metastatic calcification is usually seen at an elevated calcium-phosphate product of 70 mg^2/dl^2 (normal <40). When it occurs at normal or even at low serum calcium, it may be attributed to azotemia (previous or current), elevated parathyroid hormone levels and/or exogenous vitamin D administration.

Calcium salts get precipitated in an alkaline environment. Blood pH in the lung is more alkalotic than in other organs because of the CO_2 removal. The upper lobe predilection of some pulmonary calcific disorders, may occur due to a higher blood pH (approximately 7.51) and lower $PaCO_2$ (approximately 30 mm Hg) at the apex due to the higher ventilation-perfusion ($\dot{V}/\dot{Q}$) ratio (about 3.3 vs 0.63 respectively). Hypercalcemia and alkalosis most likely act synergistically to predispose to ectopic calcification, when other risk factors are present.

Dystrophic calcification occurs with normal serum calcium levels in the injured or the abnormal tissues. It is typically seen in granulomas and in lymphadenopathy associated with fungal diseases, tuberculosis and sarcoidosis. It has also been described in amyloidosis and after inhalation exposures in coal workers pneumoconiosis and silicosis. Injury results in caseation, necrosis or fibrosis. The calcification is most likely due to the production of 1, 25 vitamin D in the macrophages within the granulomas and increased intestinal absorption of calcium and phosphate, which provides an additive or synergistic factor that promotes calcification in these tissue.

Sarcoidosis related calcification could be dystrophic or metastatic, secondary to hypercalcemia or both. It may sometimes mimic pulmonary alveolar microlithiasis with a calcified micronodular pattern. Pulmonary Vascular Calcification (PVC) is dystrophic due to shear stress. Pulmonary Alveolar Microlithiasis (PAM) is a unique idiopathic calcific disorder with distinct histologic and

PART III: PULMONARY ALVEOLAR MICROLITHIASIS

PS Shankar

INTRODUCTION

Pulmonary alveolar microlithiasis is a rare disorder, characterized by the intra-alveolar deposition of a large number of minute calcific concretions, uniformly throughout both the lungs. Harbitz first noted in 1918, the occurrence of extensive calcification of the lungs as a pulmonary disease.[1] The condition was labelled as pulmonary alveolar microlithiasis by Pahr in 1933.[2] The cases are sporadically reported from different parts of the world including from India.[3-8]

Etiopathology

The etiology is undetermined. A local alteration in the cells of alveolar septa appears to predispose to the occurrence of calcification. There is no abnormality of calcium metabolism. The cases have been reported in age group 30 to 50 years. Females are affected more than males. There is a familial incidence with a tendency to appear in siblings.[5] A family of pulmonary alveolar microlithiasis was reported from India, where three sisters of the five siblings had the disease.[4]

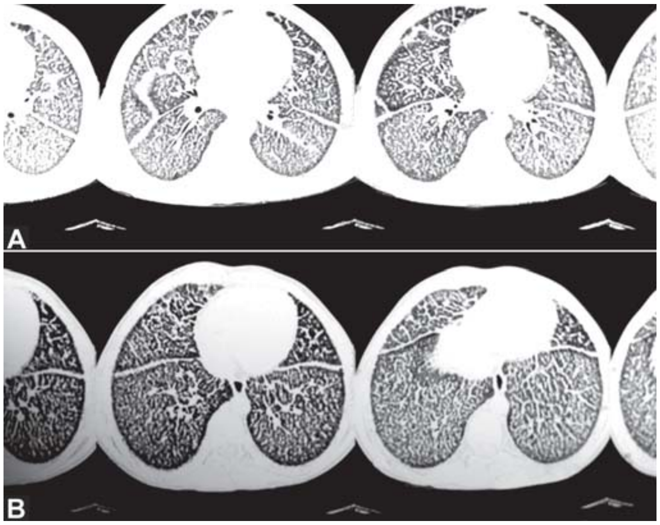
The lungs are solid containing sand-like grains (colcospherite) that are distributed diffusely, more so at the bases, a saw may be required to cut the lung.[5] Under microscope, they appear as "onion-skin" bodies in the alveoli and are densely calcified. There can be emphysematous blebs at the apices or along anterior margins of the lungs. Pulmonary interstitium is not involved. Such calcification is not encountered in other organs.

Clinical Features

Although the condition presents as abnormal chest radiograph from an asymptomatic patient, the advanced cases can present with cough, dyspnea and respiratory failure. Hemoptysis may occasionally occur[6] and very rarely calcified bodies may be coughed. There can be occurrence of recurrent pneumothoraces.[7] Physical examination of the chest often does not reveal any abnormality, even in the presence of markedly abnormal chest radiograph. In advanced stages, the disease may show the presence of inspiratory crackles and ultimately, the signs of cor pulmonale.

Investigations

The chest radiograph gives widespread snow-storm appearance from minute calcified mottled shadows. They may be so profuse, as to make the lung diffusely white, especially in mid and lower lung zones obscuring the cardiac borders, as shown in Figure 166.4A. Pleural calcification gives pencilthin sharp dense white lines along



Figs 166.4A and B: Chest roentgenograph and CT scan in pulmonary alveolar microlithiasis: Shows bilateral, diffuse distinct micro nodular, sand like mottling of lungs giving the appearance of a white lung (*Courtesy:* Dr Sanjeev Mehta)

the costal surfaces and over the hemidiaphragm. Presence of bullae may be considered to be a feature of advanced stage of disease.[4] The radiological appearance of stenosis, talc granulomatosis and calcified military histoplasmosis may simulate microlithiasis, but the lesions in those conditions are larger and have different distribution.[5]

The lungs appear like sack of sand containing innumerable homogeneous intra-alveolar deposit of calcium containing bodies. Lung biopsy reveals alveolar spaces containing aminated calcific microliths, with fibrosis and thickening of the alveolar walls.[9] Transbronchial lung biopsy is helpful to confirm histological diagnosis.[10] The spherules exhibit a concentric lamellar appearance (onion-skin bodies) implying their growth, by the addition of successive layers and contain calcium and phosphorus. Computed Tomography (CT) demonstrates extensive microcalcific deposits in the posterior and inferior subpleural spaces and along bronchovascular bundles, interstitial fibrosis and bronchiectasis. Calcified nodules larger than 1 mm (up to 5 mm) are visible on high resolution CT scans, as shown in Figure 166.4B. Thin-walled subpleural cysts, indicative of early fibrosis can be seen on HRCT images.[11] Scintigraphy shows intense uptake of radiotracer technetium 99 m by calcified spherules.[12,13]

Pulmonary function studies do not show any abnormality despite extensive radiographic changes. In the later stages of disease, there is a restrictive pattern of lung volumes due to alveolar filling and a reduction in diffusing capacity.[14] Exponential analysis of lung static pressure-volume obtained by whole body plethysmography, shows decreased lung compliance, normal shape curve and reduced extrapolated lung volume at infinite distending pressures.[15]

Treatment

There is no specific treatment. The disease is slowly progressive leading ultimately to development of chronic cor pulmonale, respiratory or cardiac failure. Nasal continuous positive-airway pressure ventilation has been tried to improve oxygenation in patients with respiratory failure.[16] Bilateral sequential lung transplantation may be other alternative.[17]

PERSPECTIVES IN PULMONARY AND CRITICAL CARE MEDICINE

SK Jindal

167

Ethics in Respiratory Care

Basil Varkey

> *"Ethics is an inherent and inseparable part of clinical medicine."*
>
> —Singer P, Pellegrino ED, Seigler M[1]

In all physician-patient interactions there is a moral component; some interactions (e.g. withdrawal of ventilator in an ICU) pose an obvious and dramatic ethical consideration while others (e.g. decisions on aggressive treatments in end stage diseases in office settings) are less obvious. Patient care decisions involve more than selecting a treatment or intervention on a scientific basis; the physician's ethical obligation to benefit the patient and to avoid or minimize harm and the values and preferences of the patient and family members are all very much in play. Competence in ethics has been shown to improve the quality of care in certain areas[2,3] and is a requisite to provide competent patient care.

SCOPE OF ETHICS

Several factors (abuses of human subjects in research, experimentation in concentration camps in World War II, advances in medicine and medical technology and societal changes) contributed to the rapid evolution of bioethics from one concerned about professional conduct and codes to its present status with an extensive scope that includes research, public health, organizational and clinical (also referred to as medical) ethics. However, because of common and familiar usage the term medical ethics or ethics, rather than the more precise term bioethics, is used in this chapter.

Current Status of Knowledge and Skills

Knowledge and skills and attitudes about ethics of practicing physicians and resident physicians are variable and often less than satisfactory. Although the obligation to respect patient preferences on care at the end of life is accepted in the United States (US), a seminal nationwide study found significant deficiencies in physician performance.[4] Another study found that physicians often failed to disclose medical errors although disclosure is an ethical duty.[3] Other studies have documented deficiencies in knowledge and skills in resident physicians.[5,6] These and similar studies along with an increased recognition of the importance of ethics in all medical professional activities and especially in medical practice have spurred educational efforts at all levels.

Ethics Education

Ethics has been included as a formal required part of curriculum for medical students in the US. The Accreditation Council for Graduate Medical Education Outcome Project has introduced a program for training and evaluation of resident physicians in six core competencies and ethical principles are a key part in the definitions of three of them: professionalism, interpersonal and communication skills and patient care. Continuing education programs are offered and in some cases required by several states; physician organizations, locally and nationally offer ethics courses. The goals of ethics education are applicable for learners at any level (Table 167.1).[7] Core behavioral skills in ethics include obtaining informed consent, assessing decision-making

TABLE 167.1: Goals for Ethics Education*
Awareness and appreciation of ethical dimension in patient care.
Understanding of core ethical principles and values of the medical profession.
Knowledge of commonly encountered ethical issues in general and specific to one's specialty.
Demonstrated competence in "core bioethics behavioral skills".
Competency in using a method for analyzing and resolving ethical problems.
Appreciation of cultural diversity and its impact on bioethics.
Willingness and ability to teach bioethics to students and trainees in clinical settings.

Reference 7 with permission.

capacity, discussing resuscitation status and use of life-sustaining treatments, advanced care planning, breaking bad news and effective communication.[7] Ethics education has been shown to improve learner awareness, attitudes, confidence, knowledge and in moral reasoning.[8,9]

The preceding discussion on the assessment of physician knowledge, skills and attitude and on education interventions, it is hoped, will provide an impetus for physicians in academia and practice in India and other developing countries to conduct similar studies with the support of their organizations and perhaps with private or governmental grant. A most desirable goal would be to introduce ethics at the undergraduate medical student level and to continue it through postgraduate training and practice.

Ethics and Morality

Ethics is a generic term covering different ways of examining the moral life. Normative ethics attempts to answer the question "Which general moral norms for the guidance and evaluation of conduct should we accept and why?"[10] Some moral norms about right conduct are common to human kind–transcends cultures, regions, religions and other group identities—and constitute common morality; examples of which include—not to kill or harm or cause suffering to others, not to steal, not to punish the innocent, to be truthful, to obey law, to nurture the young and dependent to help the suffering and rescue those in danger. Particular morality norms bind groups special because of their culture, religion, profession, etc. and include responsibilities, ideals, professional standards, etc., and the explication or adjudication in some cases may need experts or religious authorities.

Professional moralities that include moral codes and standards of practice are one form of particular morality. Physicians have specialized knowledge and training and a commitment to provide services to patients. The standards and rules of their organizations attempt to keep them competent and trustworthy so that they can fulfill their obligations to their patients. These obligations based on the accepted role of a physician then form in a basic level, the ethics of the profession. Physicians organizations have also codified their standards to reduce the vagueness of professional morality based on "the accepted role of a physician". Codes, although well-intentioned, may simplify moral requirements and may lead physicians to mistakenly consider that they are fulfilling the moral norms by complying with the codes. Critics have observed that these codes have inconsistently appealed to general ethical standards or to a source of moral authority and "has often appeared to protect the profession's interests more than to offer a broad and impartial moral viewpoint or to address issues of importance to patients and society".[11]

THE FOUR-PRINCIPLE APPROACH TO MEDICAL ETHICS (PRINCIPLISM)

Common morality, described earlier, is the base from which the 4 principles of biomedical ethics evolved. They are: (1) Respect for autonomy, (2) Nonmaleficence, (3) Beneficence and (4) Justice. The principles of respect for autonomy and justice evolved later than the other two. A notable book on medical ethics by Percival[12] written more than two centuries ago did not feature patient autonomy and justice but he did underscore the patient's best medical interest as the proper goal of medicine. In modern times Beauchamp and Childress' book on Principles of Biomedical Ethics is considered a classic for their erudite and insightful exposition of the four principles of bioethics[10] without disregarding alternative approaches.[13,14]

Respect for Autonomy

The philosophical underpinning for autonomy, as interpreted by philosophers Immanuel Kant and John Stuart Mill, and accepted as an ethical principle, is that all persons have intrinsic worth and therefore should have the power to make rational decisions and moral choices and each should be allowed to exercise his or her capacity for self-determination.

Autonomy, as is true for all four principles, needs to be weighed against competing moral principles and in some instances may be overridden; an obvious example would be if the liberty for autonomous action causes harm to another person or persons. The principle of autonomy does not extend to persons who lack the capacity (competence) to act autonomously; examples include infants and children and incompetence due to developmental, mental or physical disorder. A rigid distinction between incapacity (assessed by health professionals) and incompetence (determined by court of law) is not of practical use as a clinician's determination of a patient's lack of decision-making capacity has the same practical consequences as a legal determination of incompetence.[15]

Detractors of the principle of autonomy question the focus on the individual and propose a broader concept of relational autonomy that is a product of social relationships and complex determinants, such as gender, ethnicity and culture.[16] The differences in attitudes to disclosure of terminal illness and to decision-making at the end of life in elderly subjects of different ethnic make ups was reported in a study from California. Korean Americans and Mexican Americans were less likely than African Americans to believe that patients should be told of a terminal prognosis and less likely to believe that the family should make decisions about life support.[17]

These views, on careful consideration, do not negate the principle of patient autonomy if one appreciates that autonomous choice is a right of a patient and the patient may choose a family member or members to make decisions for him/her. Physicians have a professional obligation to ensure that their patients have the right to choose and inherently the right to accept or decline information.

Respecting the principle of autonomy also obliges the physician to disclose medical information and treatment options that are necessary for the patient to exercise self-determination. The proper understanding of the principle of autonomy supports other moral rules, such as informed consent, truth-telling and confidentiality.

Informed Consent

In order for a consent for a medical or surgical procedure or intervention or for research to meet the requirements of an informed consent, the patient or subject: (1) Must be competent to understand and decide, (2) Receives a full disclosure, (3) Comprehends the disclosure, (4) Acts voluntarily and (5) Consents to the proposed action.

The validity and applicability of these requirements, that emanated from western culture, universally to all countries have been questioned; instead it has been suggested that informed consent requirements be adapted to accommodate the cultural mores of countries.[18] In a spirited and vigorous defense of the afore listed five requirements of informed consent, Angell wrote "There must be a core of human rights that we would wish to see honored universally, despite variations in their superficial aspects—" and "The forces of local custom or local law cannot justify abuses of certain fundamental rights, and the right of self-determination on which the doctrine of informed consent is based, is one of them". She went on to pose a question whether apartheid simply represents a South African custom that is morally neutral or does it offend universal standards of justice?[19] In the matter of informed consent, the writer of this chapter is an universalist.

Since competence is the first of the requirements for informed consent, one should know how to detect incompetence. Standards (used singly or in combination) that are generally accepted for determining incompetence are based on the patient's inability to state a preference or choice, inability to understand one's situation and its consequences and inability to reason through a consequential life decision.[20]

Incompetent (nonautonomous) patients and previously competent (autonomous) but presently incompetent patients would need a surrogate decision-maker. In a nonautonomous patient either a substituted judgment standard (what would the patient wish in this circumstance not what the surrogate's wish) or a best interest standard (highest net benefit to the patient by weighing risks and benefits) can be used by the surrogate. In a previously autonomous, but presently incompetent patient the previously expressed preferences (prior autonomous judgments) should be respected even in the absence of a written formal advance directive.[21]

Truth-telling

Truth-telling, besides being a common virtue, is an obligation for the physician as it respects patient autonomy, honors the implicit contract with the patient and promotes trust. Conveying bad news, such as diagnosis of cancer and prognosis, is not an easy task. Specific instructional tools, such as standardized patient cases, observed role play and feedback are increasingly used to improve communication skills of medical students and resident physicians.

In the United States, there has been a marked shift in physicians' attitude toward full disclosure. In 1961, 88% of physicians surveyed indicated their preference to avoid disclosing a diagnosis;[22] in 1979, however, 98% of surveyed physicians were in the favor of disclosure.[23] Surveys in the United States show that patients with cancer and other diseases wish to have fully informed. While full disclosure to the patient is considered a norm in the United States, disclosure is highly variable in other countries.[24]

Cultural differences, traditional role of physician authority, and conflicts between ethical principles (discussed later) account for this difference.[25] A pattern that is not uncommonly followed, in nonwestern countries is to disclose the information to the family and not to the patient. This violates patient autonomy unless the patient chooses this option and authorizes the physician to do so. The likely reasons for the resistance of physicians to convey bad news are concern that it may cause anxiety and loss of hope, uncertainty of about the outcome, belief that the patient would not be able to understand the information and may not want to know. An autonomous patient has a right to choose not to know, but the physician must know about this choice. Providing full information, with tact and sensitivity, to patients who want to know should be the standard. The sad consequences of not telling the truth regarding a cancer include depriving the patient of an opportunity for completion of important life-tasks: writing a history for ones children, putting financial affairs in order, reconciling with estranged family members, attaining spiritual order by reflection, prayer and religious sacraments.[26,27]

Confidentiality

Physicians are obligated not to disclose confidential information given by the patient to another party without the patients' authorization. An obvious exception (with implied patient authorization) is the sharing necessary of medical information for the care of the patient from the primary physician to consultants and other health care teams. In the present day, modern hospitals with multiple points of tests and consultants and the use of electronic medical records there has been an erosion of confidentiality. However, individual physicians must exercise discipline in not discussing patient specifics with their family members or in social gatherings.[28]

There are some noteworthy exceptions to patient confidentiality. These are legally required in the reporting of gunshot wounds and venereal diseases and exceptional situations that may cause major harm to another; examples are partner notification in HIV disease and relative notification of certain genetic risks.

Nonmaleficence

Nonmaleficence is the obligation of a physician not to harm the patient. This simply stated principle supports several moral rules — do not kill, do not cause pain or suffering, do not incapacitate, do not cause offense and do not deprive others of the goods of life. The practical application of nonmaleficence is to have the physician is weigh the burdens against benefits of all treatments, to eschew those that are inappropriately burdensome and to choose the best course of action for the patient. This is particularly important and pertinent in difficult end-of-life care decisions on withholding and withdrawing life-sustaining treatment, medically administered nutrition and hydration and in the doctrine of double effect in pain and other symptom control.

Beneficence

The principle of beneficence is the obligation of physician to act for the benefit of the patient and supports a number of moral rules — to protect and defend the right of others, prevent harm, remove conditions that will cause harm, help persons with disabilities and rescue persons in danger. Note in distinction to nonmaleficence the language is one of positive requirements. The principle calls for not just avoiding harm but to benefit patients and to promote their welfare. Rather than the idealized view of physicians' beneficence as based on altruism and philanthropy, an argument can be made that it is based on reciprocity for the debt to society (education, in some instances subsidized by state governments, and privileges) and to their patients (for learning from them in practice and research).

Justice

Distributive justice is by one definition fair, equitable and appropriate distribution determined by justified norms that structure the terms of social cooperation.[29] The following principles of distributive justice, to each person, have been proposed: an equal share, according to the need, effort, contribution, merit and free-market exchanges. It is easy to see the difficulty in choosing, balancing and refining these principles to form a coherent and workable solution to distribute medical resources. This large health care policy discussion is beyond the scope of this chapter.

However, issues of justice are encountered daily in hospital practice and office practice. A few examples: allotting scarce equipment (e.g. ventilator), giving expensive drugs when the budget is tight, dealing with uninsured patients, providing a benefit not covered by insurance and even in allotting time for outpatient visits (on what basis: equal time for every patient or based on need or complexity or based on social status). Difficult as it may be and in spite of the many constraining forces, physicians must accept the requirement of fairness contained in this principle.[30]

Conflicts between Principles

Each one of the principles is to be taken as a *prima facie* obligation that must be fulfilled unless it conflicts, in a specific instance, with another principle. When faced with such a conflict, the physician has to determine the actual obligation to the patient by examining the respective weights of the competing *prima facie* obligations based on the content and context. Consider an example of a conflict that has an easy resolution: a patient in shock treated with urgent fluid-resuscitation and the placement of an indwelling intravenous catheter caused pain and swelling. Here the principle of beneficence overrides that of nonmaleficence. Many of the conflicts that physicians face, however, are much more complex and difficult. Consider a competent patient's refusal of a potentially life-saving intervention (mechanical ventilation) or request for a potentially life-ending action (withdrawing mechanical ventilation). Nowhere in the arena of ethical decision-making is conflict as pronounced as when the principles of respect for autonomy and beneficence collide.

Beneficence has enjoyed a historical role in the traditional practice of medicine. However, giving it primacy over patient autonomy is *paternalism** that makes a physician-patient relationship analogous to that of a father to a child. A father may refuse a child's wishes, may influence a child by a variety of ways – nondisclosure, manipulation, deception, coercion, etc., consistent with his thinking of what is the best for the child. Paternalism can be further divided into soft and hard.

In soft paternalism the physician acts on grounds of beneficence (and at times nonmaleficence) when the patient is nonautonomous or substantially nonautonomous (examples are cognitive dysfunction due to severe illness, depression, drug addiction).[31] Soft paternalism is complicated because of the difficulty in determining whether the patient was nonautonomous at the time of decision- making, but is ethically defensible as long as the action is in concordance with what the physician believes to be the patient's values. Hard paternalism is action by a physician, intended to benefit a patient, but contrary to the voluntary decision of an autonomous patient who is fully informed and competent. In contrast to soft paternalism, hard paternalism is ethically indefensible with very rare exceptions.

On the other end of the scale is consumerism, a rare and extreme form of patient autonomy that holds the view that the physician's role is limited to providing all the medical information and the available choices for interventions and treatments while the fully informed autonomous patient selects from the available choices. In this model, because of the limited role a physician cannot use his/her knowledge and skills to benefit the patient and therefore, partaking in this model of care is a form of patient abandonment.

Faced with the contrasting paradigms of beneficence and respect for autonomy and the need to reconcile these to find a common ground, Pellegrino and Thomasma, argue that beneficence can be inclusive of patient autonomy as" the best interests of the patients are intimately linked with their preferences" from which "are derived our primary duties to them".[32]

Several models to analyze and resolve ethical problems have been proposed. One model uses a systematic four points approach as follows: (1) Medical (identifying medical problems, treatment options, goals of care), (2) Patient (finding and clarifying patient preferences on treatment options and goals of care), (3) Quality-of-life (QOL) (effects of medical problems, interventions and treatments on patient's QOL with awareness of individual biases on what constitutes an acceptable QOL), (4) Context (many factors that include family, cultural, spiritual, religious, economic and legal). Using this model the physician can identify the principles that are in conflict, ascertain by weighing and balancing what should prevail and when in doubt turn to ethics literature and expert opinion.[7]

ETHICS IN END-OF-LIFE (EOL) CARE

Having laid the ground work on ethical principles as they apply to clinical practice in the preceding discussions, this segment will focus on aspects of particular, some of exclusive importance to pulmonary and critical care physicians. A substantial number of patients die with unrelieved symptoms that are poorly recognized and

poorly treated, physicians are often unaware of patients' wishes regarding EOL care and interventions often are not consistent with patients' preferences.[4,33] End-of-Life care demands a diverse set of physician skills (Fig. 167.1),[34] professionalism and ethics and ethically competent care is linked with quality of care.[2] Dealing with EOL issues, more than any other patient/family and physician interactions, has the potential to compromise decision-making that is influenced by the physician's personal and cultural values and religious and spiritual beliefs.[35,36]

(See Appendix 1 (Chapter 168): End-of-Life Care—Religious beliefs and practices in India)

Pulmonary and critical care physicians provide care in various milieus (outpatient, inpatient hospital, ICU) for patients with cancer and chronic life-limiting diseases, such as Chronic Obstructive Pulmonary Disease (COPD) and pulmonary fibrotic diseases. In the latter group, prognostication is difficult and therefore, it is hard to decide when to initiate advanced care planning and EOL care. The quality of EOL care in chronic lung disease is poor,[37,38] and patients with COPD are more likely to die in the intensive care unit (ICU) than patients with cancer, while on mechanical ventilation and with dyspnea.[39] In the United States approximately 20% of all deaths occur in the ICU and a substantial number of them involve a decision to withhold or withdraw life-supporting therapy.[40]

Communication and Decision-Making in EOL Care

The initial communication step for a physician is to inquire as to the patient's preference regarding decision making- self or a designated family member or members. The patient or designated family member(s) may also defer some of the responsibility, especially for a difficult decision (e.g. do not resuscitate order) to the physician.[41] In such a case, the physician is obligated to provide periodic updates and to affirm that there has been no change in the delegated responsibility. As many critically ill patients in the ICU are not able to fully participate in discussions on their own EOL care their family members often play a key role in EOL decisions. Hence, the physician should be sensitive to the stresses and burdens of the family, help them understand the clinical status and prognosis, elicit from them the patient's values, and in partnership with them develop goals of care and treatment plan that are based on the patient's prognosis, values and preferences.[42]

Sorrily, in one European study, only one half of the ICU's involved patients and family in decision making and wide variations in practice were noted between countries.[43] Even when guidelines are in place the practice patterns may vary greatly.[44] There is a dearth of information on EOL decision-making process in the ICUs from the most populous countries—India and China.

Seriously ill patients and their families identify communication skills as one of the most important skills for physicians,[45] and communication successes and failures generate more gratitude and complaints than any other aspect of EOL care.[46] Several components of communication are shown to improve quality of EOL and these along with a useful mnemonic for family conferences[47] are shown in Table 167.2.

Medical Futility and Conflicts

The concept of medical futility is controversial and the term is fraught with ambiguity. Futility can be used to cover various situations of predicted improbable outcomes, improbable success and unacceptable benefit-burden ratios.[48] Typically, the term is used in a situation in which dying patients have reached a point at which further treatment provides no physiologic benefit or is hopeless and becomes optional. "Clinically nonbeneficial interventions" has been proposed as an alternative term for futility.[49]

Invoking medical futility as the reason to withhold or withdraw life-sustaining treatments against the wishes of a patient or surrogate decision maker is ethically very problematic. Such conflicts can be substantially reduced with timely and structured communications that builds trust between physician and the patient and family. To incorporate the provision to avoid interventions of no

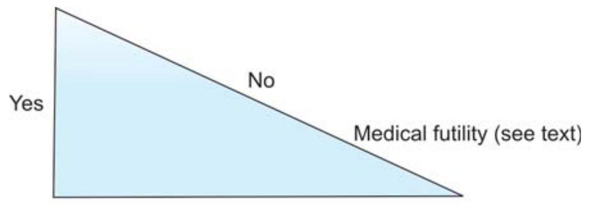
benefit (medical futility) in to a frame work of EOL decision making is essential, provided 'benefit' is defined with reference to the patient's preferences and values. An approach to such a framework is outlined in Figure 167.2.[50] The American Medical Association recommends that when a patient or surrogate decision maker insists on a therapy that the physician believes is futile, a communication and negotiation process should be started to reconcile these differences, and the treatment should be provided until the differences are reconciled.[51]

Discussion with patient/family

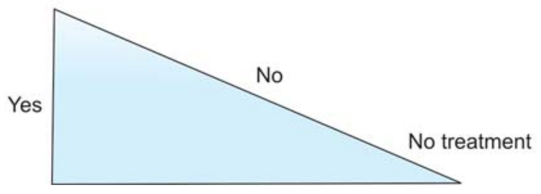
1. Elicit and understand patient's values and preferences for treatments and outcomes.
2. Formulate patient's wishes into appropriate goals of treatment and care.

Treatment decision

3. Determine whether treatment can achieve at least one reasonable treatment goal.



4. Determine whether the patient wants the treatment.



Treat and periodically reassess

Fig. 167.2: A framework for discussing goals and treatment[50]

Withholding or Withdrawing Life-Sustaining Measures

Most of the deaths in the ICU and acute care wards occur after a decision to withdraw life-sustaining treatments.[40,52,53] Some physicians are uncomfortable in withdrawing treatment that is already in place but feel justified in withholding (not started) treatment. This distinction, from an ethical standpoint is unclear and irrelevant and morally untenable.[54] Assigning a preference and priority to withholding over withdrawal can lead to under-treatment (not using it to avoid the decision to withdraw later) of some patients who may possibly benefit from it, and over-treatment (continuation of treatment that is no longer beneficial) in others.

Pulmonologists, intensivists and other physicians practicing in ICUs should understand the goals of withdrawing life sustaining treatments, and to remove all treatments no longer desired or indicated while ensuring patient comfort. Discussion with families should include explanation of the process, assurance that a palliative approach to alleviate all symptoms and to provide comfort will be provided, the expected length of survival (range and if uncertain state so) and learning of specific patient and family preferences (especially religious and cultural) prior to death.[55,56] Documentation should include the rationale for withdrawal of life-sustaining treatments, plans on how the procedure will be done and how complications, if any, will be handled.

Modalities such as vasopressors, antibiotics, nutrition can be discontinued without a taper. As abrupt mechanical ventilation withdrawal may cause discomfort from dyspnea and secretions a protocol for ventilator withdrawal[57] and a protocol for analgesia and sedation[58] should be followed. There is no set upper limit for the sedative and analgesic drugs used in this setting as symptom control is the overriding objective (see the following section under Doctrine of Double Effect). Moreover, higher dose of opioids and benzodiazepines used in the context of withdrawal of ventilator has not been shown to decrease the time from withdrawal to death.[59]

The reasons for the use of increased sedation and analgesia and monitoring of symptoms and treatments used from withdrawal of life sustaining-treatment until death should be documented. Prior to the withdrawal the family should be given time to say good bye to the patient and after withdrawal and control of symptoms the family should be allowed to be with the patient.

Doctrine of Double Effect (DDE)

This doctrine makes a distinction between intended effect and unintended but foreseen effect of a single act that has double effects— one good and one harmful. Under the DDE, if the action satisfies four elements it is morally permissible.[60] The four elements are: (1) The nature of the act, (2) The intention of the doer, (3) The distinction between means and effects, and the proportionality between the good effect and the bad effect (the bad effect is permissible only if the intended good effect in proportionality more than the bad effect). The classic clinical situation in which DDE comes into play is in severe symptom (e.g.: pain, dyspnea) management in EOL. In this context, the physician's obligation and intention to relieve the suffering of the patient by appropriate drugs such as opioids, overrides the foreseen but unintended harmful effects or outcome.

Meeting the Needs of the Family

In acute care settings, especially in ICUs, the needs of family members of the patent are largely unmet.[61] The modern ICU is not designed to be family-friendly. Family members are often excluded from the bedside.[62,63] Supportive and compassionate care to the family from physicians and other health care providers fall short due to factors that include- lack of role-models, deficiencies in attitude and skills, competing demands for time and constraints placed by hospital or by the physical layout of the ICU.

To meet the basic and minimum requirements of the family, any ICU anywhere in the world, should provide- a designated place/room (with chairs and toilet facility) for family members to rest, periodic updates on the patient's condition and access to the patient. Policies regarding visitation restrictions, that are generally more stringent in ICUs the developing world, should be reexamined. Issues that need to be addressed include: Are some of the restrictive policies more for the convenience of the health care providers than for patient benefit? Are risks of infections (not influenza, coryza and other viral infections) transmitted from the family to the patient proven and quantitated? Do these risks outweigh the positive benefits to the patient to have a loving family member at the bedside?

Culturally Sensitive Care

Culture is commonly defined as the customary beliefs, social forms and material traits of a racial, religious or social group and has a clear influence on the group's values, perspectives and decision-making. Recognition of culture-based differences that may exist between physician and patient is a critical step in providing culturally sensitive care[64] and skillfully managing these differences improves patient and family satisfaction and may also lead to a better outcome.[65]

However, this critical step of recognition of culture-based differences should be based on communication and the expressed opinions of the patient and not on assumptions based on religion, caste, race, socioeconomic status, gender or age. Cultural differences are also present, as expected, between countries and as a consequence some practices of medical ethics of the western world are either not accepted or resisted in other parts of the world; examples are the moral and legal equivalence of withholding and withdrawing life-sustaining treatment (previously discussed) and the definition of brain death.[66,67]

Resistance to some of the basic principles of ethics, such as patient autonomy—in nonwestern cultures is not unexpected. In countries with ancient civilizations, rooted beliefs and traditions, such as in India, the practice of paternalism by physicians emanated from beneficence. However, in the present times, a critical examination of paternalistic practice is needed for reasons that include technological and economic progress of the country, improved educational and socioeconomic status of the populace, globalization and societal movement towards emphasis on an individual than to a group. This needed examination can be accomplished only by research that includes well-structured surveys on demographics, patient preferences on who the decision-maker is, informed consent, truth-telling, confidentiality, EOL decisions and surveys of physicians on these same topics as well as their demographics, education in ethics and perceived barriers to practice based on ethical principles.

One major component of culturally sensitive care is respecting and accommodating the religious beliefs of the patient and family.[68-70] This is particularly important in EOL care when death is imminent. Prayers and rituals provide solace to the patient and family. Policies in ICUs and wards should be flexible within reason to honor rituals and prayers specific to the dying person's religion. At times, a simple provision for a ritual (e.g. sipping Ganges water) may be all that is needed to fulfill the last wish of a dying patient.[71]

A NEW COVENANT AND A CONCEPTUAL MODEL FOR PATIENT CARE

A New Covenant

The Hippocratic oath, attributed (authorship is questionable) to Hippocrates (460–370 BC), expressed physicians' obligations to patients of beneficence (to help the sick) and nonmaleficence (never to use it to injure or harm them). In more recent times, it has come under critical review for "sexism, secrecy, self-aggrandizement and sorcery".[72] Moreover, ethical issues of truthfulness, distribution of health care resources, safeguard of research subjects are not addressed and thus the Hippocratic oath, that enjoyed a long run of continuity until the 20th century, is inadequate and outdated.

Robin and McCauley[72] proposed a new oath relevant to modern times with 16 elements. Although I agree with all the elements, I have selected a few that are consonant with the theme of this chapter, and underscore some of the points I have made, and together they form an appropriate new covenant for physicians. These are:

1. I will remain a student all my professional life, attempting to learn not only from formal medical sources but from my patients as well.
2. I will attempt to function as a teacher for my patients so that I can care for them more effectively and can apply the lessons they provide to the care of other patients.
3. Knowing my own inadequacies and those of medicine generally, I will strive to cure when possible but to comfort always.
4. I will do unto patients and their families only what I would want to be done unto me or my family. I will not experiment on patients unless the patients give truly informed consent. I will strive to instruct patients fully so their informed consent is possible.
5. I will be honest with my patients in all medical matters. When this honesty reveals bad news, I will deliver it with understanding and sympathy and tact.
6. I will provide my patients with acceptable alternatives for various forms of diagnosis and medical and surgical treatment, explaining the risks and benefits as best I know them.
7. I will allow my patients to make the ultimate decision about their own care. In circumstances where my patients are incapable of making decisions, I will accept the decision of family members or loved ones, encouraging them to decide as they believe the patient would have decided.

A Conceptual Model for Patient Care

Drawing upon a life-time experience as a physician and teacher of physicians, I present a conceptual model of patient care in Figure 167.3. This model requires a physician to be both competent and virtuous and integrates elements in the text. Morality, both common and particular, and ethical principles have already received due attention in this chapter. The focal virtues expected of a physician (also applicable to other health care professionals) are depicted in the figure.

Compassion, a prelude to caring, combines an active regard for another's welfare with an imaginative awareness and emotional response of sympathy, tenderness and discomfort at another's misfortune or suffering.[73] Compassion presupposes sympathy and is expressed in acts of beneficence as in relieving pain and suffering.

Discernment is the ability to make fitting judgments and reach decisions without being unduly influenced by extraneous conditions and while keeping personal emotions in check. A discerning physician will thus recognize even in the face of conflicting options when comfort is paramount and provide the right type of consolation and care to the patient. Discernment is a particularly valuable virtue in situations where principles of ethics collide.

Trustworthiness leads to a good climate of trust between people, when trust is taken to be acceptance of being to some degree and some respects, in another's power.[74] Trustworthiness is an essential virtue as patients, at a time when they are most vulnerable and needy, place themselves in the hands of their physicians.

Integrity involves the coherent integration of one's emotions, knowledge and aspirations while being faithful to one's moral values and defending them when necessary. A person is deficient in integrity if he or she lacks firmly held moral convictions or fails to act on the one's convictions. Physicians will need to practice with both professional integrity and personal integrity. In the former, adherence to not only professional standards that are codified but also adherence to moral and ethical principles that may not be codified (examples are prescribing drugs that are not effective, placing monetary gain over patient's welfare, inappropriate relationships with patient, treatments without informed consent) are called for. A physician's personal integrity based on religious and moral convictions may face a challenge in

some clinical situations (examples are abortions, removal of life-sustaining treatments); in such situations the physician, in defense of one's moral convictions, can refuse to participate in action that compromises his or her integrity. However, these situations can be avoided or at least reduced by anticipating these problems; if facing such a situation is unavoidable, any adverse impact on the patient must be prevented by using institutional resources (policies, consultation, ethics committee) and delegation of care to another physician.

Conscientiousness is the virtue that motivates a person to do what is right, after diligently determining what is right. Conscience is not a special moral faculty and does not confer a self-justifying moral authority; rather it is an internal checking mechanism requiring critical reflection on good versus bad, right versus wrong and obligatory acts versus prohibited acts.

The virtues of compassion, discernment, trustworthiness, integrity and conscientiousness are the necessary building blocks for the fundamental virtue of caring. Caring is the defining virtue for all health care professionals and there is no greater duty for a physician than patient care. Francis Peabody, in 1927, in the last sentence of his memorable article used this simple yet profound definition " the secret of the care of the patient is in caring for the patient".[75]

End-of-Life Care

Jeba S Jenifer, SK Jindal

End-of-life (EOL) care is an interdisciplinary clinical domain, which most physicians find stressful and challenging. Subtly, medical science has implied that death always reflects poorly on the skills of the health care providers, a failure on their part to save life. Death should not be viewed as a failure of medical care, but rather an inevitable natural course. Most certainly, all health care professionals should be able to provide good quality, compassionate and effective palliative care for their patients.

The American College of Chest Physicians supports the position that good quality palliative and EOL care should become an integral part of cardiopulmonary medicine.[1] The World Health Organization (WHO) defines palliative care as *"the active total care of patients whose disease is not responsive to curative treatment. It is the approach that improves the quality of life (QOL) of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual"*.[2] QOL can be defined by its inverse relationship to the difference between an individual's expectations and his perception of the given situation, the smaller the gap the better QOL (Fig. 168.1).[3]

There is no clear consensus definition for EOL. Unfortunately EOL care is considered synonymous with palliative care. EOL care is a subset of palliative care, providing support and care more towards the terminal phase. Many principles and aspects of palliative care are applicable earlier in the course of an illness, in conjunction with disease modifying therapy and supportive care (Fig. 168.2). It is also important that palliative care continues to provide bereavement support. Importantly, the EOL is heavily dependent on cultural, social and religious beliefs and practices.

(See Appendix 1: EOL Care—Religious Beliefs and Practices in India).

PROGNOSTICATION

Identifying the EOL phase is a challenge and requires the clinical skill of prognostication. The transition into this phase may be very acute or subtle, depending on the disease and varies for malignant and non-malignant diseases (Fig. 168.3).

The illness trajectory in cancer is often a predictable decline until death, whereas in chronic respiratory diseases, such as Chronic Obstructive Pulmonary Disease (COPD), the clinical course is usually a slow deterioration, punctuated by dramatic exacerbations, that often ends in unexpected death. Arguably, the greatest challenge to provision of EOL care in COPD is the unpredictable disease trajectory, as compared to that of cancer. Moreover, in cancer, often there is maintenance of good functional status until a short period, with a predictable decline in the last weeks or months of life.[4] However, it is important to understand that death may occur prematurely without recognition, when good EOL care is impossible.

BARRIERS

The most important barrier that precludes provision of good EOL care is the difficulty in prognosticating and the chance of unexpected death. Sometimes, there is a prejudice amongst doctors and patients that COPD as well as lung cancer is usually self-inflicted diseases due to smoking and that they do not deserve measures to improve QOL.

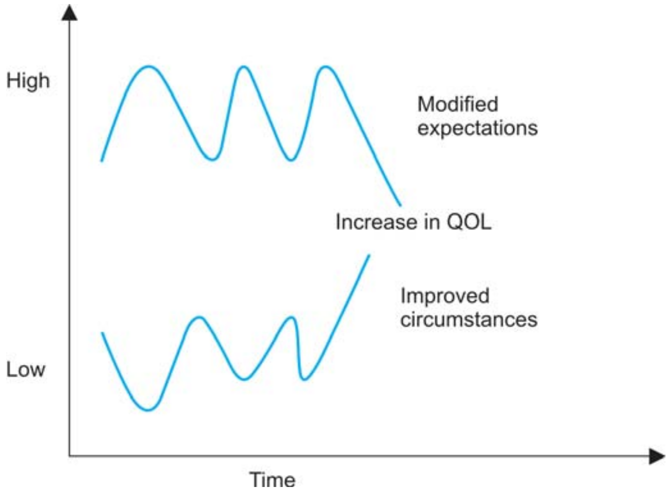

Fig. 168.1: Quality of life

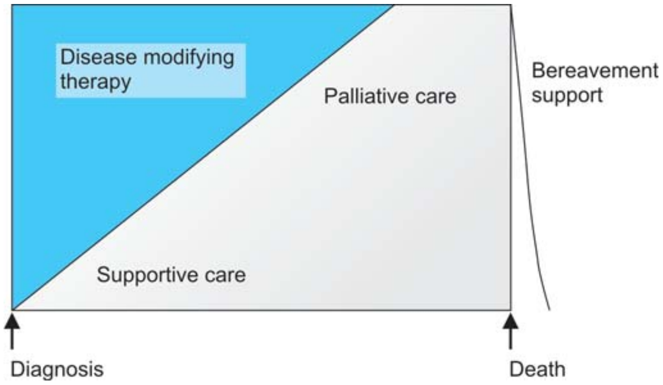

Fig. 168.2: Relationship between disease modifying therapy, supportive and palliative care

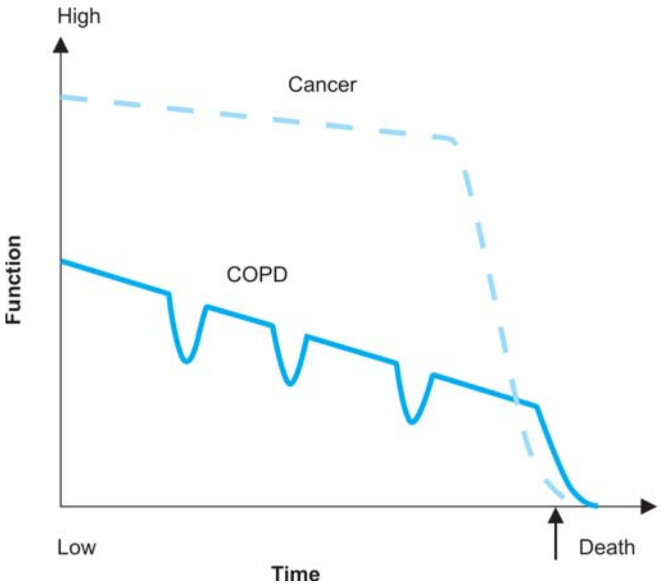

Fig. 168.3: Difference in illness trajectory in malignancy and COPD

Patients with chronic lung diseases at the EOL have physical and psychosocial needs at least as severe as patients with lung cancer.[5] Despite these needs, it has been reported that none of the end-stage COPD patients were offered or received input from palliative care specialists, while 30% of the lung cancer patients had received such care and 56% were aware of these services.[6] It is common for patients with COPD to have had a primary care visit or been admitted in ICU in the last 6 months of life and to have spent a significant time in their last six months in hospital.[7,8]

Breathlessness, fatigue and anxiety are more common in COPD than in advanced cancer, heart disease or renal disease,[9] but they are less likely to receive medication for symptom control, as compared with lung cancer patients.[8] This occurs despite the fact that most COPD patients prefer treatment focused on symptom control rather than on prolonging life and COPD patients are equally as likely as lung cancer patients to prefer not to receive cardiopulmonary resuscitation.[10] Although the reasons for this discrepancy are not entirely clear, it could be due to poor or infrequent patient-physician communication about EOL care and treatment preferences.[11]

Despite the existing barriers and difficulties, it is crucial for the health care team to identify the EOL phase and adopt a sensitive and structured approach of care.

COMPONENTS OF EOL CARE

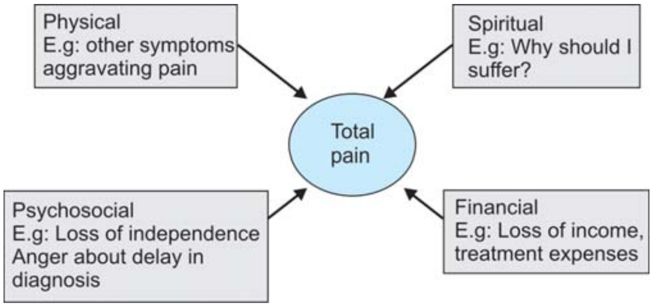
Providing care at the EOL is not simply continuing all that was done before. EOL care focuses on symptom management, preservation of QOL, active communication with patients and carers and support of the physical, psychosocial and spiritual well-being.[12] It ensures that the supportive and palliative care needs of the patient and family are identified and met throughout the last phase of life and through bereavement.[13] There is ample evidence, mostly from cancer patients, that delivery of palliative care is associated with reduction in pain and other symptoms, improvements in QOL with enhanced family and patient satisfaction.[14-18] Inputs from hospital-based palliative care services are also associated with significantly lower likelihood of admission to ICU and lower inpatient costs.[19] Unrelieved symptoms and unmet needs can result in bitter memories and would be difficult to forget for relatives.

COMMON SYMPTOMS IN EOL

One of the essential components in EOL care is achieving maximal symptom control. Pain, breathlessness and fatigue are present in more than 50% of patients with end-stage respiratory disease.[9] Anxiety and depression are more common among COPD patients than among patients with lung cancer, 90% versus 52%, respectively.[6] Coexisting depression may play a significant role in EOL decisions and treatment preferences for life-sustaining therapies.[20] Patients with COPD and other lung diseases also have reduced health related QOL, with physical, emotional and social functioning significantly affected.[21-24]

Pain

The prevalence of pain among lung cancer patients attending the outpatient services and those using palliative care services is 27 and 76%, respectively. The pain may relate to cancer (73%) or to treatment (11%); nociceptive in nature in the majority, although 30% can have neuropathic pain.[25] Pain is often ignored and remains an uncontrolled symptom, as many physicians focus on ordering an array of investigations and making diagnosis and fail to prescribe analgesics at the appropriate dose and frequency. Although pain is a physical symptom, various aspects relating to pain should be addressed, to ensure "total pain" relief (Fig. 168.4).



Physical
E.g: other symptoms aggravating pain
Spiritual
E.g: Why should I suffer?
Total pain
Psychosocial
E.g: Loss of independence
Anger about delay in diagnosis
Financial
E.g: Loss of income, treatment expenses

Fig. 168.4: Concept of total pain

Comprehensive pain evaluation, routine assessment, appropriate analgesic prescription and titration until adequate pain relief, are requisites for optimal pain management.[26] Inadequate treatment of pain is often because of poor pain assessment and discrepancy between patient and physician's assessment.[27] Joint Commission on Accreditation of Healthcare Organizations Standards require that all inpatient and outpatient health care facilities should systematically assess and document pain.[28]

The WHO cancer unit has developed simple analgesic prescribing guidelines, which constitute the gold standard in cancer pain management and an effective method to ensure rational titration of analgesia.[29] It is encouraging to know that by correctly following WHO analgesic ladder, pain can be controlled in nearly 90% of cancer patients.[30] Patients and families can be assured that pain can be relieved safely and effectively in the majority. The WHO analgesic ladder can be used for the treatment of pain in advanced chronic lung diseases.

The WHO analgesic ladder recommends the use of analgesics for all patients with pain on a regular basis, orally, in the right dose and frequency with analgesics given appropriately for breakthrough pain. Whenever possible, the oral route is preferred as it is convenient, non-invasive and cost-effective. The choice of analgesia should be based on the pain severity in a step-wise fashion and not on the stage of disease (Table 168.1).[31] To prevent side effects of opioids, prophylactic antiemetics and laxatives should be prescribed. This would enhance patient compliance. In mild, moderate and severe pain, Steps 1, 2 and 3 should be used, respectively. In Step 1 a non-opioid [Non-Steroidal Anti-Inflammatory Drugs (NSAIDs) or paracetamol] should be used. Step 2 includes a non-opioid and a weak opioid and Step 3 a strong opioid and non-opioid. NSAIDs should be avoided in patients with significant upper intestinal tract bleeding, renal failure, platelet dysfunction and those on anticoagulants.[32]

Opioids should be used at a reduced dose in the elderly and at a reduced frequency in those with renal/hepatic failure. Adjuvant analgesics which produce analgesic effect in some painful conditions, can be combined with any of the steps, especially for control of neuropathic pain (e.g. corticosteroids, tricyclic antidepressants, anticonvulsants). Palliative radiation therapy should be considered in patients with advanced lung cancer for pain relief.

An audit on pain assessment and analgesics prescription for cancer patients in a respiratory ward at a tertiary hospital in South India, revealed that educational interventions (teaching, provision of pocket guidelines and use of posters) improved analgesic prescription patterns.[31]

Dyspnea

Dyspnea is a distressing and frightening symptom to both the patient and the carers. The incidence of dyspnea among advanced cancer patients during the last six weeks of life is as high as 70%.[33] It significantly affects the physical, emotional and social well-being and results in poor QOL.[34] It is an important prognostic factor and predicts poor survival in cancer patients.[35,36] As a refractory symptom, it is associated with a five time increased probability of sedation at EOL.[37]

The three treatment categories in a patient with dyspnea include the correction of the correctable, use of

TABLE 168.1: Guidelines for pain management

WHO analgesic ladder with sample prescriptions

Step 3 (severe pain)
Tab Meloxicam 15 mg od
Tab Morphine 5 mg q4h and prn**
(titrated upwards if needed)
Tab Metoclopramide 10 mg tid
Tab Bisacodyl 10 mg hsod

*Non-opioid + strong opioid + / - adjuvant**

Step 2 (moderate pain)
Cap Proxyvon 1 q6h or q8h and prn (max 8 per day)
(**or** Tab Tramadol 50–100 mg q6h or q8h)
Tab Meloxicam 15 mg od
Tab Bisacodyl 5 mg hsod
Tab Metoclopramide 10 mg prn

*Non-opioid + weak opioid + / - adjuvant**

Step 1 (mild pain)
Tab Meloxicam 15 mg od
(**or** Tab Paracetamol 1 gram qid)
Cap Proxyvon 1 prn.

*Non-opioid + / - adjuvant**

Proxyvon is a combination of Dextropropoxyphene 65 mg and Paracetamol 325 mg.
* In patients with neuropathic pain, spinal cord compression, bone pain use of adjuvants/appropriate referral for expert opinion should be considered.
Analgesics should be given at the right dose, at the right time (round the clock at the right frequency), by the right route (oral).

Oral morphine prescribing guidelines
(For more information - http://www.jpalliativecare.com/documents/oralmorphine.doc)
Morphine should be given with a non-opioid.
Start with 5 mg q4h (unless patient is already on opioids **)
For break through pain, give an extra dose (same as the 4 hourly dose) up to 1–2 hourly
Do not omit the next regular dose, if a prn dose has been given.

Always……
Prescribe a stimulant laxative prophylactically
(e.g. Tab Bisacodyl 10 mg at night. Do not use bulk laxatives such as Naturolax.)
Prescribe an antiemetic prophylactically for the first few days.

****Morphine when patient is on opioids:**
If a patient is already taking > 4 capsules of Proxyvon, the starting dose would be at least morphine 5–10 mg q4h.

Increasing morphine dosage:
If pain is not controlled or > 2 prn doses are needed per day,
increase by approximately 50% of the starting dose
OR
Recalculate q4h dose based on total used in previous 24 hours.
If the oral route is no longer practical → Give **half** the dose by subcutaneous injection (10 mg per oral = 5 mg subcutaneous)

If pain is nonresponsive
- Check compliance
- Is the patient taking drugs prn only?
- Have you got the cause right?
- Does the opioid dose need to be increased?
- Is there a neuropathic element?
- Are psychosocial aspects being neglected?
- Will treatment of side effects permit more of analgesics?
- Will an alternate route of administration help?

Contd...

Contd...

Adverse effects

- Sedation can be common at the start of treatment, but resolves within few days.
- When starting the patient on opioids, use Tab Metoclopramide 10 mg q8h × 3 days.
- If patient is constipated on opioids even with bisacodyl 10 mg hsod,
  - consider bisacodyl 10 mg tid, along with a softener (e.g: cremaffin 15–30 ml tid)
  - If problem persists, intervene early with rectal measures
  - rectal examination to rule out impaction
  - bisacodyl suppository
  - high glycerine enema
  - digital rectal evacuation.

non-pharmacological interventions and use of drugs to palliate dyspnea (Fig. 168.5). Dyspnea could be related to the disease, the treatment or to other comorbidities. In advanced cancer patients, the cause of dyspnea is often multifactorial.[38] It is important to identify and treat the common reversible conditions in malignant and non-malignant respiratory diseases (Table 168.2). A cochrane review on the role of non-pharmacological interventions for breathlessness in advanced malignant and non-malignant diseases showed that neuro-electrical muscle stimulation, chest wall vibration, walking aids and breathing training are beneficial.[39] Other non-pharmacological measures can also be tried (Table 168.3). A respiratory physiotherapist should be part of the team offering EOL care, particularly for advice on non-pharmacological treatment.

Symptomatic treatment is indicated when there is no clear underlying correctable cause, the disease specific treatment is ineffective, difficult to tolerate or not consistent with patient preference. In advanced respiratory disease due to interstitial lung disease or COPD, palliative drugs are indicated when standard treatments including pulmonary rehabilitation, bronchodilators, antibiotics, corticosteroids, Long-term Oxygen Therapy (LTOT) or non-invasive ventilation have failed to relieve dyspnea or are not feasible on a long-term basis. There is strong research evidence from trials and from Cochrane review, for the use of oral and parenteral opioids to treat dyspnea in both malignant and non-malignant respiratory diseases. Nebulised morphine is not effective.[40, 41] Morphine can be used to reduce the sensation of dyspnea and relieve distressing tachypnea (Table 168.4). The side effects of morphine need to be addressed prophylactically. Morphine when used judiciously, with careful titration does not produce respiratory depression (i.e. does not increase CO_2 retention).[42,43] During the terminal phase of life, dyspnea and anxiety can worsen, with an increasing chance of delirium, this should be managed as per laid down principles and guidelines (Table 168.5).

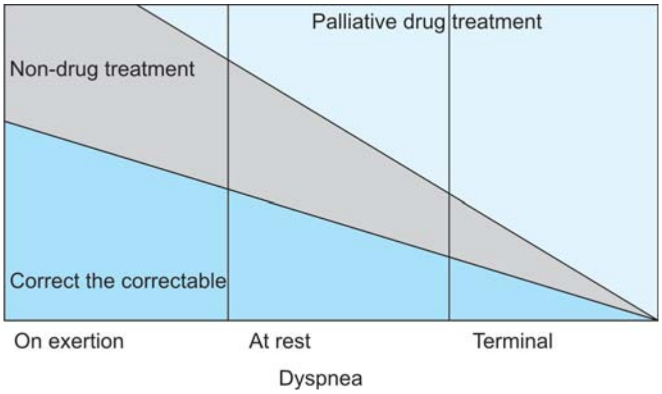


Fig. 168.5: Treatment of dyspnea

TABLE 168.2: Correctable causes of dyspnea in EOL

Typically in advanced cancer	*Typically in advanced respiratory disease*
Pleural/pericardial effusion	Pneumothorax
Superior vena cava obstruction	Pneumonia
Pneumonia	Pulmonary embolism
Pulmonary embolism	Anemia
Anemia	Cardiac failure
Cardiac failure	

TABLE 168.3: Non-pharmacological treatment for palliation of dyspnea

Explanation—symptom, acknowledge and address anxiety
Education—handling sudden episode of dyspnea/panic, activity pacing.
General measures—keep window open, use fan, loose clothing around neck.
Breathing techniques
Chest physiotherapy
Relaxation therapy
Pulmonary rehabilitation

Anxiety often coexists with and significantly affects the intensity of dyspnea, resulting in a vicious cycle.[44] Benzodiazepines are considered useful where there is significant anxiety or panic attacks that worsen dyspnea.[45] Combination of benzodiazepine with opioid is often found better than using either of them alone.[46] Benzodiazepines probably help through anxiolytic and sedative effect and possibly muscle relaxation. Care should be taken with diazepam, as it can accumulate due to its long half-life. Lorazepam (1–2 mg) is shorter acting and when given sublingually, provides immediate relief, hence especially useful during panic attacks. The cochrane review recommends the use of benzodiazepines as a second or third-line treatment within an individual therapeutic trial, when opioids and non-pharmacological measures have failed to control dyspnea.[47]

Most COPD patients receive regular bronchodilators. In cancer patients, bronchodilators are useful for the associated bronchospasm. Bronchospasm is found in more than half of dyspneic cancer patients.[38,48] A combination of inhaled short acting beta-2 agonists and anticholinergics are helpful.

Use of oxygen is not routinely indicated in advanced cancer. A Cochrane review clearly failed to demonstrate any benefit with inhaled oxygen in patients with end-stage malignancy.[49] Blowing cool air over the face with a fan is useful. A trial of oxygen can be considered if the patient remains breathless, even with drugs to palliate dyspnea (including morphine) and with persistent hypoxia. Oxygen should be given at 2 liters/ min via nasal prongs.[50] The patient should be reassessed after 24 hours and oxygen should be stopped if symptomatic response is not satisfactory.

In COPD patients with hypoxia, LTOT involving continuous oxygen use for more than 15 hours/day, is well established to enhance QOL, reduce sensation of dyspnea and improve survival.[51-53] If the patient does not satisfy the criteria for LTOT, giving oxygen only for palliation of dyspnea does not appear to have any benefit. Despite this lack of evidence of benefit, most breathless patients approaching EOL are commenced on oxygen. This practice should be strongly discouraged.

Before initiation of oxygen, the pros and cons should be tightly weighed on an individual basis. Patients can become psychologically dependent and may become anxious whenever oxygen is stopped. The oxygen equipment limits mobility and the mask impairs communication. Oxygen inhalation causes dryness of nasal mucosa. Risk of combustibility and added cost are the other negative factors in oxygen use. So if oxygen is used outside the indications for LTOT in COPD patients or on a trial basis in cancer patients, it should be used on an N-of-1 randomised controlled trial.[54,55]

TABLE 168.4: Guideline on the use of morphine for palliation of dyspnea

In patients who are opioid naive
(Patients who have not been on dextropropoxyphene (Proxyvon), tramadol, codeine, morphine, fentanyl)
- For mild dyspnea, prn doses of immediate-release oral morphine 2.5 mg will suffice
- In others, start with immediate release oral morphine 2.5 mg q4h and as required
- After 24 hours, if little or no improvement, increase to 5 mg q4h and as required
- Assess further response and titrate with 30–50% dose increments
- Relatively small doses should suffice 2.5–10 mg q4h

For patients already on round the clock regular morphine
Increase morphine dose based on the severity of dyspnea:
- Moderate dyspnea, give morphine at a dose equivalent to 50–100% of the q4h analgesic dose
- Severe dyspnea , give morphine at a dose ≥ 100% of the q4h analgesic dose
- Reassess and titrate with 30–50% dose increments.

Extreme dyspnea and distress
- Give morphine 2.5 mg subcutaneous (SC) followed by midazolam 2.5 mg SC (If the patient is not improving seek advice from specialist palliative care physician).

TABLE 168.5: Management guidelines for severe terminal dyspnea

- Convert oral to SC morphine (use half the oral dose)
- Increase the dose by 30–50% if the dyspnea was previously uncontrolled (round to the nearest 5 or 10 mg). Consider adding midazolam 10 mg as a continuous SC infusion over 24 hours
- In addition give haloperidol 2.5 mg at night OR along with the morphine and midazolam continuous SC infusion over 24 hours
- Extra prn doses of midazolam 2.5 mg SC with morphine 5 mg SC may be needed
- When reviewing after 24 hours the dose of morphine and midazolam may need to be revised in the light of the extra doses given
- Patients who are very old, very debilitated or who have severe renal or hepatic failure need dose reduction
- Other medications should be reviewed on a daily basis and simplified
- Explain to family that the intent is to reduce distress associated with breathlessness.

Cough

Cough is a normal but complex physiological mechanism that protects the airways and lungs by removing mucus and foreign matter from the larynx, trachea and bronchi; it has both voluntary and involuntary control. Pathological cough is common in those with cardiothoracic disorders and can be quite distressing. It is present in more than half the patients with chronic lung disease or lung cancer.

Cough can be classified as productive, with or without the patient being able to cough effectively and non-productive. Several causes of cough may coexist in one patient.[56] Management of cough depends on the type and cause of cough, the patient's performance status and prognosis. One should aim to reverse the cause of cough, whenever possible. Non-pharmacological measures like physiotherapy, teaching the patient to cough effectively and steam inhalation may be helpful. Simultaneously appropriate drugs to produce sympton relief should be prescribed. The choice of drugs would primarily depend on whether it is productive or non-productive cough, to aid or suppress expectoration respectively. Protussives include, nebulized saline, compound benzoin tincture, menthol, guaifenesin, carbocisteine. Anti-tussives include simple tinctur (demuscent) and opicid (codeine/morphine) and opioid derivatives like dextramethorphan. [57]

Hemoptysis

Massive hemoptysis in advanced lung cancer and chronic lung disease is rare, but can be very frightening and visually traumatic. The cause of hemoptysis in malignant or non-malignant situations is not always established. Management depends on the cause and prognosis. If this occurs in a patient who is otherwise terminally ill, with palliative goals, the treatment aims to reduce awareness and fear. Use dark towels (green or red) to cover blood. Being physically present with the patient continually is very supportive. Benzodiazepines (diazepam or midazolam) can be given parenterally to reduce panic and awareness, intravenous route is preferred if there is peripheral vascular shutdown.[56]

Stridor

Stridor is a harsh inspiratory wheezing sound heard due to the obstruction of the larynx or of major airways. Corticosteroids can be exceptionally beneficial in the initial stages. Dexamethasone can be given in high doses (8–16 mg/day). However, the symptom will progress and worsen if the primary cause is not reversible. Explanation to the patient and the carers is crucial. In the terminal phase, sedation can be used after discussion with the relatives.

The Last 48 Hours

During this period, patients may experience increasing weakness and immobility, loss of interest in food and drink, difficulty in swallowing, and drowsiness. This phase although usually anticipated can sometimes be rapid and sudden. It is important to identify the features of dying, such as increasing weakness, being sleepy, less interest in getting out of bed, in things happening around, confusion and occasionally features of agitated anguish. Confusion and restlessness are not uncommon. Haloperidol or benzodiazepines can be used to calm the patient.

Symptom control and family support should take priority. The drug chart should be studied with regard to the need and route of administration, as most patients may have difficulty to take by mouth. Only the essential drugs that would help in symptom control or patient comfort should be continued. Previously "essential" drugs like vitamin and iron supplements, antihypertensives, hypoglycemics, etc. may not be needed anymore. Analgesics, antiemetics, sedatives may form the new "essential" list.[58] The route of administration should be decided based on patient's ability to take orally. Drugs may need to be given parenterally, preferably by subcutaneous (SC) route. A microdrip set or a syringe driver can be used to give the drugs as SC infusions depending on its availability.

Various EOL care tools like the Liverpool care pathway, Gold Standards framework enable an optimised standard care to be delivered.[59,60] A customized EOL tool/pathway can be developed, based on the concepts in these various tools and modified to suit the local condition to ensure good EOL care.

Death Rattle

Death rattle is the noisy rattling breathing that occurs during the terminal phase. The secretions in the hypopharynx oscillating with every inspiration and expiration are responsible for the rattling noise.[61] This symptom can be very frightening and distressing to the carers. It is important to explain to the family/carers that the patient is unaware and not distressed. Positioning the patient semi-prone will help in drainage of secretions. Antimuscarinics reduce production of secretions and are hence helpful, if started early before the rattle is well established. The drugs commonly used include, hyoscine butyl bromide (20 mg SC q8h) or as infusion (maximum of 120 mg over 24 hours) or glycopyrronium (200 microgram stat and

600–1200 microgram over 24 hours) through subcutaneous infusion. Oropharyngeal suction should not be routinely used and should be reserved for unconscious patients.

EOL Care in the Intensive Care Unit (ICU)

Most patients who die in the ICU die as life-supporting measures are withheld or withdrawn.[62,63] Decisions surrounding life-sustaining treatments can be difficult, because they often involve complex ethical decision-making. Refusal of life-prolonging therapy may result in conflict of interests among medical professionals or between the medical professional and patient/family, over one-third of clinicians reported conflicts with families, of which 63% constituted EOL decisions.[64] Physicians may agree to the family's inappropriate demands for aggressive life prolonging therapy because they may be worried that angry families will sue if therapy is withheld (although this fear does not have any legal justification) or may not want to put the family through tough decisions or may not be fully convinced themselves.

In India, EOL decisions have additional challenges.[65,66] Discussion about patient's preferences on treatment during EOL or the use of advanced directives is not common. In such an instance it is the family members who decide the EOL issues for the patient. Often, family members are not well-informed or do not want to take any decision themselves. A vast majority is poor and many families end up selling all their property or take loans just to spend on their relative in ICU, often losing their assets and their loved one at the end.[67] A common cause of conflict with families is poor communication. Most conflicts can be avoided by facilitating communication through a formal family conference. Family meetings are an opportunity to foreshadow EOL discussions and allow family members to psychologically prepare themselves for the bad news. Effective communication improves family satisfaction, clinical decision-making and the psychological well being of family members.[68,69]

It is crucial to make the family feel that they are cared for and not abandoned at any stage. Non-abandonment (or fidelity) is also a central moral obligation of a physician.[69] Families need to be assured that the patient is not abandoned and will receive appropriate, competent care, regardless of the stage of his or her illness. It is also important to ensure that decisions to forgo a particular treatment are not seen as with drawing care.

Communication

Physician-patient communication about EOL decisions and treatment preferences is crucial. There is evidence that patients with chronic lung disease receive suboptimal palliative care largely due to insufficient communication with their physicians. It is important to note, that nearly all patients want information on EOL decisions and life support, less than 50% of patients had EOL care discussions and most patients felt that the physicians did not discuss about how long the patient had to live, what dying might be like or patient's spirituality.[70, 71] As accurate prognostication in an individual will remain difficult due to the variability inherent with chronic lung diseases, educating patients and families about the uncertainty in prognosis of lung diseases must be an essential feature of EOL care and decision-making.[72]

There are many patient and physician related factors that are barriers to effective communication and understanding them would be the first step towards better communication.[73,74] It is good to communicate with patients and their carers about prognosis and establish goals of care as early as possible. It is important to check with the patient about their willingness to know more about their disease status/prognosis. There are different steps in disclosing any bad news (Table 168.6) and the discussions can go over many visits, depending on each patient. During such communications, it is not uncommon to encounter denial, collusion or an angry patient/relative.[75,76] Further discussion with a colleague/team in dealing with the situation will be helpful.

Discussing EOL care or giving bad news can never make a clinician feel good. The most important principle is to do it in a sensitive manner and at the individual's pace. Most patients/caregivers want some discussion at the time of diagnosis of an advanced, progressive, life-limiting illness or shortly after.[77]

Support to the Caregivers

Anxiety and depression are common among caregivers of patients with terminal illnesses. The primary caregivers must be informed of the prognosis (with permission from the patient) and must be educated on the cause, importance and management of symptoms at home. They should also be warned of the likely ways the patient may deteriorate or die. Throughout the period, they should be provided with psychological and spiritual support. They should be informed of the support services which are available. Support to the caregivers should continue

TABLE 168.6: Steps in disclosing bad news (could be diagnosis or prognosis)

Preparation

1. Review in detail patient's medical record, including disease status, treatment options and prognosis prior to starting the discussion.
2. Review your own feelings and prepare yourself.

Physical setting

1. Ensure maximal privacy possible
2. Allow patient and key family members to be present

Disclose the information

1. Check with the patient if he/ she wishes to know
2. Elicit patient's understanding by asking the patient to say what he/ she already knows about their disease (listen and understand patients feelings/expectations)
3. Give a warning shot (e.g. *"I am afraid the tests are not good", "The situation is more serious than we think…")*
4. Pause….give time
5. Give small bits of information in lay language keeping in pace with the patient
6. Be honest always. (Be ready to say "I do not know" or "I will check and let you know")
7. Check outpatients understanding on the information given.

Following the disclosure

1. Be sensitive to patients emotions (sadness, anger, fear)
2. Respond to patients emotions, give non-verbal support and active listening (eye contact, touch when appropriate)
3. Follow patient-led agenda
4. Allow silence, give patient time to react
5. Give hope tempered with realism
6. Invite questions
7. Try to summarize the discussion and make a follow-up plan
8. Clarify your role in future medical care
9. Finally document the discussion, with details about the people present, content of discussion and future directions. This will help the others in the team to continue to provide the best care.

through bereavement.[78] Good support to the patient and family by a multidisciplinary team at the EOL will enable patients to spend their final days in their preferred places of care.

ACKNOWLEDGMENT

We would like to acknowledge the contribution of Dr Reena George (Professor and Head, Palliative Care Unit, Christian Medical College and Hospital, Vellore, India) and Dr Robert Twycross (Director, palliativedrugs.com Ltd, UK) for their input into formulating management guidelines on pain/dyspnea.

APPENDIX 1: END-OF-LIFE CARE—RELIGIOUS BELIEFS AND PRACTICES IN INDIA

HINDUISM

SK Jindal

The traditional Hindus believe in the continuity of life after death. There is a great degree of sanctity attached to the pre-death worship, performance of last rites and to the rituals both before and after the death. It is strongly believed that the type and mode of death is an important determinant of the peace for the immortal soul ever thereafter. An easy and peaceful death is crucial to attain *nirvana* or *mukti*, i.e. liberation from the sufferings and miseries of the life and the death cycle.

The terminal care therefore essentially focuses to achieve the 'best possible' quality of life without interfering with the attempt to prolong the life. There is supreme importance of 'care beyond cure' and to 'dying with dignity'. Factually, the Hindu concept of life is centered around respiration and the length of life is measured by the 'limited' number of breaths which are fixed. Many a life-prolonging treatments, especially the artificial continuation of breathing with the help of ventilators are therefore in direct conflict with the traditional viewpoint. This, I believe is applicable only for artificial continuation of life in an otherwise dead (e.g. the brain-dead) individual than for assisted respiratory support as a mode for treatment.

Palliative treatment in Hinduism is quite in conformity with the existing concept of terminal care which involves the 'care beyond cure' philosophy. One aims to prevent, relieve or soothe the symptoms of disease without affecting a cure. The pre-terminal (and terminal) care is designed to offer symptomatic relief from the pain and suffering of approaching death. It is not a substitute or an alternative to curative treatment, but only an acceptance of the inevitability and of the limitations of life-prolonging treatments.

Rituals and Rites

Both the individual and the family are generally concerned with the last wish acts, and rituals near the death. Death in the bed is analogous to death of the sick which must be avoided. A dying individual is preferably moved to the floor—not for cardiac massage but to lie in the lap of mother-earth. Verses from the holy books such as the Gita or the Vedas are sung and the water from the sacred rivers, especially the Ganges is made available. The dying does like to bless the children as much as they like to be blessed. There is no better death for a Hindu elder than to die with everyone of the progeny around.

After-death handling of the body is both sacred and ceremonial. It must be properly cleaned and bathed. Nice and preferably new clothes, sometimes including the jewellary are worn before consigning the body to the flames.

Bereavement

Generally speaking, the degree of emotional attachment and inter-dependence is high in Hindu families. A sudden, or even a slow exit of a member of the family is mourned and remembered for long. The period required for resolution of grief is longer. It is possibly for this very reason that a number of sacred acts are undertaken afterwards. For example, the body remains and ashes are collected on the 3rd day or so and immersed in a sacred river. Several other functions are undertaken in the next two weeks and at fixed intervals in the following year.

ISLAMIC RITES AND RITUALS
As per Islamic Principles
(Qur'an and Shariyat as Observed in India)

M Sabir

Prophet Mohammed(s) strongly advocated to take treatment for diseases till last in addition to prayers from the 'Allah Almighty'.

Death

- Separation of the material element from the non-material element (Soul).

The soul (Roohh) departs without being perceived or even felt at the time of death. Death *marks the end of the earthy life & the beginning of eternal life.*

Just before Death

- A Muslim is supposed to clear all his dues before death, which he might owe to others.
- Pray for forgiveness from God.
- Always wishes to utter last word Kalimah—L*a Ilaha Illa Allah ho Muhammadur Rasulallah,* e.g. solemn affirmation of his faith in one God and Prophet Mohammed(s) as is his messenger.
- Recital of Holy Qur'an by relatives.

Just after Death

- Dead body is kept at a clean and honorable place, wrapped in a clean cloth.
- All external tubes, needles, secretions, blood, pus etc on body to be cleaned.
- Eyes and mouth should remain closed. For closing mouth sometimes a strip of cloth is used to bring both jaws in approximation.
- Dead body is kept in supine position with both limbs kept straight (both big toes may be tied).
- Weeping and crying by relatives is not taken good as per Islamic teachings.
- Earliest cremation is preferred (even in the night).
- Before cremation, body is given bath with soap and water (plain/scented); dried up with a peace of clean cloth and wrapped in a clean cloth- Kaffan (traditionally white);
- Specific short prayer (Namaz-e-janaza) is offered for the peace of departed soul before burial in the grave.

Sura-ar-Rahman Al Qur'an

- He has created man.
- He has taught him an intelligent speech
- The sun and the moon follow courses (exactly) computed
- And the herbs and the trees both (alike) bow in the adoratives
- Then which of the favours of your Lord will ye deny?

THE SIKH TRADITIONS

KS Bhatia

First accept death and then life.
Even I and God incarnate die.

These 'sloks' from Shri Guru Granth Sahib define death that is end of life for all living beings.

In Sikh religion, death is transition from one world to the unknown other world; almost all the religions subscribe to this theory and have different rituals.

Once it is clear that a patient is going, a doctor should take steps to ease the anxiety of the patient and do his best to see that patient accepts the coming situation. The most important thing is that the patient should not be removed from his bed and all rites and rituals should be performed in a very subtle way and an atmosphere of divinity and peace be created around the patient.

In Sikh rituals, only very close friends and relatives remain with the dying person and try that the patient accepts what is happening—not all the dying patients accept his fate. Even when a patient is in coma, recitation of *Japji Sahib, Sukhmani Sahib* from Shri Guru Granth Sahib are recited. This sooths the body and soul of the dying patient and also stops the friends and relatives from crying and weeping. An Ardas to the Almighty *Waheguru* is performed with prayer to grant peace to the dying patient.

We all know that dying is very important part of life and we have to make it as peaceful and dignified as possible. Only the recitation in the name of *Waheguru* Akalpurkh can give that. Recorded tapes of Japji Sahib and Sukhmani Sahib be played in a low volume near the patient and prayer be offered till the end.

THE JAIN RITES

VK Jain

Jainism understands the process of dying as that of changing clothes.

Jains believe in reincarnation/rebirth and transmigration (movement from one life to another) of soul.

Jain leaders, relatives, family members visit the dying person to give the family solace (consolation), relief and support.

Monks and nuns if present in the vicinity may come to see the dying person. They sing hymns particularly the Namokar Mantra—a hymn for surrendering to the liberated souls.

They explain temporary nature for the physical body and all worldly attachments.

They encourage dying person to have noble thoughts, ask to think about forgiveness for anything they have done that was not life enriching during their life and to forgive all beings who have done wrong to them and have a peaceful death.

Scriptures like Kalpasutra, Samayasar and Uttaradhyan sutra are read for comfort and consolation.

Some Jains may choose to do a *santharo,* which is renunciation (giving up of all material possessions and attachments to people) and total acceptance of death for spiritual upliftment, where all life supports are removed including food and water.

This is a voluntary practice (willed death) one may choose when at the end-stage but must be conscious.

Prayers and Devotional Songs are Chanted

Audio-video cassettes may be used to accompany religious practices. The santharo is generally done away from the hospital. It is a personal choice done with the advice of a spiritual leader.

After Death

Family members participate in the process of preparing the body by washing and dressing the body in new clothes.

Prayers are continuously chanted.

A lit lamp burning with clarified butter may be kept in the room with a dead body.

Different Jains may or may not use flowers during this time

After death the body is cremated and the whole community may come to the cremation.

Family members and relatives usually take bath either at cremation place or at their homes.

Jains usually do not believe in sorting bone ashes at cremation place or surrender/immerse ashes in Ganga or any other rivers.

Usually third day of death after attending temple or religious leaders/

Feeling and Desires of a dying person:

- May afraid of death due to possible pain in dying process.
- Some deny for mortality.
- May be religious, non-religious and anti-religious.
- Desire to have place and funeral death.
- Feeling of helplessness, hopelessness, worthlessness, guilty, sadness, suicidal ideation, all are indication of depression.

CHRISTIAN RITUALS AND PRACTICES

George D'Souza

The Church does not support, euthanasia as life is a gift from God and He alone has a right to do what he pleases with it. But the Church is not for keeping a patient alive with extraordinary means when it is futile. It recognizes the ability of modern science to do so. It also recognizes the need that these resources may be better utilized for another with a better chance of living.

The Church also supports organ donation. Pope John Paul the II recognized its importance "man has found a way to give of himself of his blood and of his body, so others may continue to live". It does not compromise our beliefs. Instead it sees it as a true act of Christian charity.

The Church reminds us constantly of death and Ash. Wednesday is the day to take shock of ourselves and to remind us of the temporary nature of an individual's existence on earth—*dust thou art to dust thou returns*. But it also gives a hope in the resurrection of Christ.

There are certain sacraments, which are administered to the sick and the dying. The sacrament of reconciliation of penance remits all sins, however, grievous by sanctifying grace. The sacrament of anointing of the sick helps a patient cope with his suffering and gives him the strength to do so. The holy Eucharist is the sacrament, which unites one with Christ. The last sacrament is the sacrament of Viaticum, which prepares one for the final journey. A priest usually administers these. In his absence any Christian could say a prayer in place of the last sacrament.

Death for a Christian is meant to be an end of his travails on earth and the beginning of a new and glorious life in Christ our Lord. As written in the book of revelations "I heard, a voice from heaven saying Blessed are the dead who from now on die in the end. They will rest from their labors for their deeds follow them".

Health Economics of Pulmonary Care

C Sudheendra Ghosh

INTRODUCTION

Cost-Effectiveness Analysis (CEA) is a technique of selection from amongst the competing wants, wherever the resources are limited. CEA was first applied to health care in the mid-1960s and was introduced with enthusiasm to clinicians in 1977 by Weinstein and Stason.[1] Since then, these approaches have been widely understood and accepted by the key decision makers in the health care sector, including the physicians. As a result, important health benefits or cost savings have been realized. This has altered the way we practice medicine and exchange information in the background of dynamic explosion of scientific knowledge. Science-based technology and availability of new therapies have provided us an opportunity to sustain life of many of our fellow human being.

Economic evaluation and deductive reasoning form the foundation for solutions to many clinical problems. We understand how subtle changes in many different genes can affect the function of cells and organisms. Uncertainty in clinical decision-making creates the need for probabilities and other quantitative tools like meta-analysis, decision analysis and cost-effectiveness analysis.[2] This is further facilitated by Evidence-Based Medicine (EBM). EBM refers to integration of best available research evidence with clinical judgment and experience in the care of patients.

A basic principle of economic analysis is that choices must be made between alternative uses of resources, and these decisions must consider for both the cost and the outcome. Trade-off and choices are inevitable since there are not enough resources to provide all the medical care that is technically possible or that patient prefers to receive. In the economic analysis of health care, there are three dimensions that need to be discussed:

1. The perspective of the analysis.
2. The type of costs involved.
3. The type of analysis considered.

The Perspective of the Analysis (Who Pays and Who Gains)

The costs, the outcomes, and the benefits can be differentially seen from the point of view of the society, the patient, the hospital authorities and the insurance agencies. For example, the cost to the insurance agency for critical care equals the charges that are allowed by that payer. The cost to the hospital is the true cost of providing critical care, regardless of the charge. The hospital's true economic cost can be found out only by carrying out a cost finding exercise. Cost to the patients is the amount they pay for the service plus the time missed from the work. The cost to the society is the total net cost of all of the different components of society, including the patient's productivity and the expenses involved in giving and receiving intensive care.

The Types of Costs Involved

Economist would define cost of critical care as the consumption of a resource that otherwise could have been used for another purpose. Since, the resource has been used for intensive care, the opportunity to use it for another purpose is lost. Therefore, its value in the next best use, which is no longer possible, is called "opportunity cost". Fixed cost is the investment required for setting up the intensive care unit. Variable cost is the expenditure required for the day-to-day management of the patient in the ICU.[4] This will vary with the volume of service.[3]

Resources used and their costs have been traditionally divided into direct and indirect costs. "Direct" generally refers to charges in resource-use attributable to the intensive care treatment, the term "direct" is used in economics to refer to productivity gains or losses related to illness or death.

i. *Direct cost:* Direct costs include the value of all the goods, services, and other resources that are consumed for the provision of intensive care treatment. These costs are often thought of as involving a monitory transaction. Direct cost involves physician time, nursing time, supportive staff time, equipment cost, procedure cost, lab cost, drug cost and costs for other consumables required for the ICU management. Direct non-health care cost includes increase in total costs required by a dietary prescription, and the cost of ambulance transportation, etc.
ii. *Indirect cost:* These are: (a) the cost associated with the lost or impaired ability to work or to engage in leisure activities due to morbidity and (b) lost economic productivity due to death.

The Type of Analysis

i. *Cost identification analysis:* It tries to find out the cost of providing Intensive Respiratory Care Unit (IRCU) care.[5] The result is expressed in terms of cost per service provided. Here, one may calculate the cost per case treated of IRCU. As an example, cost identification study may indicate the average daily cost of an ARDS patient in the IRCU as ₹ 5000, that of COPD patient as ₹ 4000 or that of pneumonia patient as ₹ 2000, it does not evaluate what these expenditure bring in terms of health outcomes.[6]
ii. *Cost-effectiveness analysis (CEA):* CEA is the structured process of evaluating the strength of evidence, incorporates both costs and effect of the treatment.[7] It measures the net cost of providing care as well as the outcomes obtained. Outcomes are reported in a single clinical unit of measurement such as a life saved. One may calculate the cost per year of life saved using noninvasive ventilation compared to ventilatory support in ICU setting. The cost-effectiveness of ICU management strategy needs to be compared with an alternative way of providing care. The reference case analysis is conducted from the societal perspective and accounts for benefits, harms, and costs to all parties. Although, CEA does not reflect every element of importance in health care decisions, the information it provides is critical to informing decisions about the allocation of health care resources.[8]
iii. *Cost utility analysis (CUA):* It is a form of cost-effectiveness analysis where the outcome measurement combines several outcomes on a common scale like Quality Adjusted Life Years (QALYs). Here, both duration and quality of survival are combined.[9] Measurement of QALYs weighs year of life by the quality of these years, which is determined by the presence of intangible outcomes such as pain and breathlessness. The QALY is a measure of health outcome which assigns to each period of time a weight, ranging from zero to one, corresponding to the quality of life during that period, where a weight of I corresponds to perfect health and a weight of 0 corresponds to a health state judged equivalent to death. The result is expressed as cost per unit of QALY.[10]
iv. *Cost-benefit analysis (CBA):* Cost-benefit analysis takes the analysis beyond measuring effectiveness in clinical terms or abstract concepts of utility. Cost-benefit analysis forces and explicit decision about whether the cost is worth the benefit by measuring both in the same units' viz. in Rupees. Cost-benefit analysis incorporate calculation of net benefit for net cost by subtracting cost from benefit. Program with larger net benefit is preferred. One may try to find out the net benefit of establishing an intensive critical care unit for the adults compared to neonatal intensive care unit.[11]

The Basics of CEA

Cost-effectiveness analysis is a technique for comparing the relative value of various therapeutic strategies. In its most simple form, a new treatment is compared with current practice (the "low-cost alternative") in the calculation of the cost-effectiveness ratio: It is also worthwhile to recognize that CEA is only relevant to certain decisions. There are various ways to how a new therapeutic strategy might compare with an existing approach (Table 169.1). Note that a CEA is relevant only if a new strategy is *both* more effective and more costly (or both less effective and less costly).

$$\text{CE ratio} = \frac{\begin{array}{c}\text{Cost of new strategy} -\\ \text{Cost of current practice}\end{array}}{\begin{array}{c}\text{Effectiveness of new strategy} -\\ \text{Effectiveness of current practice}\end{array}}$$

TABLE 169.1: Conditions under which CEA is relevant

Effectiveness	*Cost of new strategy high*	*Cost of new strategy low*
New strategy more effective	CEA relevant	Adopt new strategy
New strategy less effective	New strategy is dominated	CEA relevant

Estimating Cost-effectiveness of Self-management in COPD

There is emerging evidence that disease management with self-management education provided by a care-manager might benefit COPD patients. We evaluated the cost-effectiveness of Self-Management (SM) education among previously hospitalized COPD patients. The conventional treatment involved is inhaled medication with combination of long acting tiotropium and fluticasone; the other group received self-management education along with the conventional treatment. One year follow-up of study patients showed that the healthy days gained with conventional therapy were 289 days while that for SM therapy were 339 days. The estimated average cost for conventional therapy for one year was ` 6750.00 per patient and for SM patients it was ` 10555.00 (Table 169.2).

The result might be considered as the "price" of the additional outcome purchased by switching from current therapy to the SM treatment (e.g. ` 76 per disease free day). If the price is reasonable enough, SM can be considered "cost-effective" and a good value. Being cost-effective does not mean that the strategy saves money. Similarly, just because a strategy saves money does not mean that it is cost-effective. The very notion of cost-effectiveness requires a value judgment-what you think is a good price for an additional outcome, someone else may not.

Quality of Life and Outcome Assessment Measures

Quality of life (QOL) has been defined by the World Health Organization (WHO) as an individual's perception of his position in life in the context of the culture and value systems in which he lives and in relation to his goals, expectations, standards and concerns. It is a broad ranging concept incorporating in a complex way the person's physical health, psychological state, level of independence, social relationships, personal beliefs and their relationship to salient features of the environment.

The WHO QOL group instrument is organized into six broad domains of quality of life. These are: Physical domain; psychological domain; levels of independence; social relationships; environment; and spiritual domain. Within each domain a series of subdomains (facets) of QOL summarize that particular domain of quality of life.[12]

With the cost utility analyses, the cost of an intervention is related to the number of quality adjusted life years (QALYs). A QALY is a year of full life quality. Poor health may reduce the quality of year (e.g. from 1 to 0.5). Here, each life-year is quality-adjusted with a utility value, where 1 is equal to full health. The utility value aims to reflect the health-related quality of life. Different types of interventions are then compared by calculation of costs per gained QALY.

Disability adjusted life years (DALYs) is a combined measure of years in disability and years of life lost due to premature death (from the disability).[13] Two mathematical equations are used to calculate DALY-Years of Life Lost (YLL) and Years Lived with Disability (YLD). YLL is the number of years of life lost due to premature death. YLD is the number of healthy years lost due to disability from the condition until remission or death. These are then summed together to provide years living with disability. The DALY scale range is the reverse of the QALY scale, with 1 indicating death and 0 indicating the best possible state of health. Unlike QALY, DALY reverse scaling would not allow for negative values because 0 is equivalent to perfect health. The calculations for DALY consider age and sex when calculating the burden of the disability; there is no consideration for economic status so that disability burden is measured globally for all.[14]

TABLE 169.2: CEA-examining conventional treatment and SM therapy in COPD

Strategy	*Cost in Rs*	*Incremental Cost Rs.*	*Effectiveness-(No of HDG)*	*Incremental effectiveness*	*CE RATIO*
Current	6750.00	-	289.00	-	-
Self-management	1055.00	3800.00	339.00	50.00	` 76/HD gained

TABLE 169.3: Common instruments to measure QOL in Pulmonary Medicine

Instrument	*Measure*
St. George's Respiratory Questionnaire (SGRQ)	3 aspects (activity, symptoms, impact)
Medical Outcome Study Short Form 36 (SF-36)	8 dimensions
World Health Organization Quality of Life (WHO QOL) assessment instrument	24 aspects of QOL
EuroQOL 5-D (EQ-5D).	5 dimensions

Health-related Quality of Life Instruments

Health status or health-related QOL assesses the influence of disease on physical, emotional, and social functioning. In contrast, the core of QOL is the person's perception of his or her life. QOL has a much wider scope than the physical, emotional and social domains.

There are several available instruments to measure QOL of patients with lung diseases (Table 169.3).

The St. George's Respiratory Questionnaire (SGRQ) measures three aspects (activity, symptoms, impact) and the medical outcome study short form-36 (SF-36) has 8 dimensions, whereas the World Health Organization Quality of Life (WHO QOL) assessment instrument measures 24 aspects of QOL. QOL encompasses the respondent's own perception of aspects of their life, while health status asks respondents about the presence or frequency of behavior and feelings.[2] However, in choosing between the SGRQ, the medical outcome study short form-36 (SF-36), and the WHO QOL, it will be important that researchers decide what domains are important in a particular study: Quality of life or health-related quality of life and generic or disease-specific. Furthermore, for studies in which both domains are important, it will be important to have head-to-head comparisons of the instruments measuring the reliability, validity, and responsiveness of each.

The difference between QALY and QOL measures is the dynamic of measurement. QALY attempts to provide a method of measurement for the impact of disease or treatment on an individual's ability to function and it can be equated to an economic scale. QALY measures differ from the QOL measures that provide subjective information describing individual's self-perception of their health status at a particular point of time.

Quality of Life with ILD

Chang et al.[15] studied the usefulness of four health-related QOL instruments, two generic and two respiratory-specific measures, in a group of interstitial lung disease patients [33 Idiopathic Pulmonary Fibrosis (IPF), 10 sarcoidosis, and seven miscellaneous], and concluded that the medical outcome study short scores from all four QOL questionnaires correlated significantly with 6 min walk distance and dyspnea score. Scores from the SF-36, QWB, and SGRQ showed significant correlation with FVC, FEV_1, and diffusing capacity as well. Patients with IPF appear to have similar impairments in HRQL to those with chronic obstructive pulmonary disease.

Other studies of HRQL in patients with IPF suggest that, in addition to the obvious effect on physical health, general health, energy level, respiratory symptoms, and level of independence are also impaired.[16] Variability in HRQL among patients is not fully explained by measures of dyspnea or pulmonary function, suggesting that HRQL measures provide unique information.[17]

CONCLUSION

The choice between the quality of care vis-a-vis its costs poses a persistent dilemma for the physicians. On one hand, they must serve as advocates for the individual patient and recommend the course of action most likely to be beneficial to the patient. On the other hand, physicians must understand the cost as well as the benefits of medical interventions so that they can choose amongst the wide range of options. Exponential growth in technology, the remarkable capability of modern pulmonology and its increasing availability (including in this country) have created many ethical and economic issues. Neither medical necessity nor expected medical benefit nor economic evaluations give us a decision procedure for resolving these distributive problems. Economic evaluation offers more complete information relevant to our decision.

Surgery for Tuberculosis and Infective Lung Conditions

RK Dewan

Most of the thoracic surgery developed in the late 19th and early 20th century, specifically dealt with the management of Tuberculosis (TB) patients. The same challenges were also encountered while dealing with various other infective lung conditions. The management strategy for tuberculosis progressed from isolation and fresh-air sanatoria to various surgical collapse techniques and surgical resection. Surgical therapy was perfected in the mid-1950s, but subsequently declined with the emergence of effective antitubercular chemotherapy. Thereafter, reports of surgical intervention for tuberculosis have been extremely rare especially from the western countries. Most of the literature in thoracic surgery after 1960s dealt with carcinoma lung with occasional exception of tuberculosis and other infective lung conditions.

HISTORICAL ASPECTS

There is a fascinating history of development of surgery for lung diseases, which helps us to better understand their rationale and changing role in the present scenario. A Roman physician, Gorgio, in 1696, reported that a TB patient had improved dramatically after he suffered a sword wound in his chest, which produced a pneumothorax. This started the concept of collapse therapy. Carson, in 1822, suggested that something must be done in order to force the diseased lung to rest artificially by external means. Forlanini, an Italian physician, observed in 1890 that lung collapse tended to have a favorable impact on the disease outcomes. This ended the depressing era of helplessness in the face of advanced TB. Later, many other surgical procedures, e.g. artificial pneumoperitoneum, phrenic crush, plombage, thoracoplasty and resection followed. In the post-chemotherapy era, introduction of successful antitubercular chemotherapy decreased the need of surgical intervention. Most TB surgeons took toward developing cardiac surgery. The need for surgery in India, on the other hand, always remained considerable due to sheer number of cases. With Multidrug Resistant Tuberculosis (MDR-TB) and Human Immunodeficiency Virus (HIV), the west rediscovered interest in the subject. In the post-globalization phase, publications of interest are coming from former Soviet Republics, Japan, Italy, Hungary, Turkey, Argentina, Peru, Pakistan and elsewhere.[1-6]

There are several infective conditions of the lung that may warrant surgical management (Table 170.1). In all these conditions, the spectre of HIV [Acquired Immunodeficiency Syndrome (AIDS)] has added new dimensions, challenges and complexities in the past two decades. Tuberculosis with or without HIV remains the single most important challenge. Since there are no randomized prospective studies, surgical recommendations for surgery are based primarily on case reports, retrospective studies, experience and consensus.[7] The management of tuberculosis as well as of other infective lung conditions is primarily medical, surgery being resorted to only in occasional cases (Table 170.1).

There are three main categories of indications for surgery in TB (Table 170.2). These include the following: (1) Diagnostic procedures to confirm TB and to rule out other causes including cancer; (2) Excision surgery to remove worrisome disease in drug resistant cases; and (3) Emergent or urgent therapy to control life-threatening hemoptysis, or relieve a septic process.

TABLE 170.1: Infective diseases of lungs which may often warrant surgical management

- Tuberculosis, especially its complications and sequel
- Bronchiectasis
- Lung abscess
- Empyema
- Pleural complications of amoebic liver abscess
- Post-traumatic infective and inflammatory conditions in chest
- Latrogenic complications like esophageal perforation
- Lung abscess not responding to medical management
- Postoperative complications of thoracic and cardiac surgery
- Diagnostic problems in thorax

TABLE 170.2: Indications of surgery in tuberculosis

- Diagnostic
- Persistent sputum positive state despite therapy
- Complications and sequel:
  - Hemoptysis
  - Destroyed or bronchiectatic lungs
  - Empyema with or without bronchopleural fistula (BPF)

Indications in most of the series suggest that the evolving considerations are ruling out cancer, failure of chemotherapy, sequel/destroyed lung, failed operation, hemoptysis, MDR-TB, pleural disease and aspergilloma.[8]

TYPES OF SURGICAL PROCEDURES PERFORMED FOR TUBERCULOSIS

There have been many surgical procedures which had been used in the past or are being currently used for the diagnosis and management of tuberculosis. These can be classified as under:

Procedures of Historical Interest

1. Sandbag/diseased side down.
2. Pneumothorax, artificial.
3. Intrapleural pneumonolysis; apicolysis (injection of air, or paraffin-oleo thorax), utilizing open or thoracoscopic approach of Jacobaeus.
4. Pneumoperitoneum.
5. Multiple intercostal neurectomy to decrease costal excursions.
6. Scalenectomy to decrease upper costal excursions and to depress the lung apex.
7. Phrenic nerve crush or paralysis.
8. Transection of accessory muscles of respiration (scalenotomy).
9. Extrapleural plombage of pneumothorax (space between parietal pleura and endothoracic fascia); (injection of air, nitrogen, paraffin wax).
10. Subcostal and extraperiosteal plombage (bird cage) (periosteum stripped from upper five ribs). Lucite balls are most commonly used.
11. Caverostomy (Monaldi Procedure).
12. Thoracoplasty (staged).

Some of these procedures are still occasionally used, at least in the developing countries.

Diagnostic Procedures

1. Thoracocentesis.
2. Transthoracic needle aspiration.
3. Closed/open pleural biopsy.
4. Bronchoscopy (flexible/rigid), transbronchial needle aspiration.
5. Mediastinoscopy/anterior mediastinoscopy (Chamberlain procedure).
6. Thoracoscopy (Video-assisted thoracic surgery).
7. Exploratory/diagnostic thoracostomy-wedge biopsy.

Therapeutic Procedures

1. Decortication—with or without lung resection.
2. Drainage (closed/open) (temporary/permanent); pleurocutaneous window.
3. Thoracotomy with resection
   - Segment/wedge
   - Lobectomy
   - Pneumonectomy (transpleural; extrapleural; completion).
4. Chest wall/vertebral body-disc resection/ stabilization.
5. Muscle flaps (myoplasty).
6. Thoracoplasty (modified/tailored).
7. Omental transfer.

Persistently Active Disease

The decision about proper case selection is the most important in this situation. There is a justified indication for surgery in only some of the selected cases. These situations are:

1. The disease is sufficiently localized.
2. Adequate trial of antitubercular treatment (ATT) has been given.
3. Drug failure.
4. Patient is chronic secretor.

These are broad indications for surgery in patients of MDR-TB or persistent sputum positive status. There are

TABLE 170.3: Specific indications for surgical intervention in persistently active pulmonary tuberculosis

- When sputum smear or culture is positive for AFB, despite 4-6 months of appropriate and supervised Anti-Tuberculosis Treatment (ATT)
- When there have been two or more relapses
- One or more relapse while on therapy
- The organism has been shown to be resistant on culture and sensitivity
- When the patient is likely to relapse in the judgment of the physician
- Anticipated non-compliance in an admitted patient after discharge

a few other specific situations where surgery is a good adjuvant in the management plan of persistently positive active disease (Table 170.3).

Surgery plays an important role in the overall management of MDR-TB with acceptable mortality and morbidity.[9-13] Surgical interventions, in carefully selected cases, along with 2nd line ATT appear as the most favorable option since even the best available medical therapy alone provides bacteriological cure only in the order of 44 to 77% vis-à-vis more than 90% success rate with adjuvant surgery. Thoracoplasty is a useful approach for persistently positive cavitary disease (Fig. 170.1). Operative mortality is no longer a prohibitive issue, with most series reporting less than 3% early mortality. Though operative mortality has decreased, significant morbidity continues to remain a nagging problem, with Bronchopleural Fistula (BPF) in association with empyema formation being the most distressing manifestation. In cases of thoracic surgery, poor nutritional status and sputum positivity at the time of surgery are associated with a higher rate of complications.

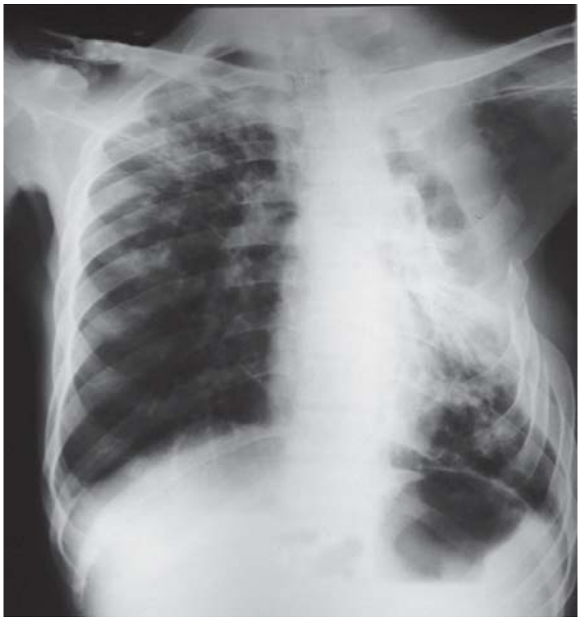

Fig. 170.1: Postoperative X-ray of a patient who has undergone thoracoplasty for persistent sputum positive status

Consensus lacks regarding the application of perioperative ATT. The rationale behind selecting the exact timing of intervention needs to be logical and scientific. Whereas it appears logical to use surgery after a defined induction phase of chemotherapy, a scientifically defined induction phase has yet to be worked out. Generally accepted timing of surgery is after 3 months of carefully prescribed 2nd line ATT, achieving optimal bacterial suppression at the time of surgery, yet avoiding delay to a point where the bacillary load is at a perilous high. Continuation of drugs for 18–24 months postoperatively seems reasonable by most authors, although given the economics involved, completion of this task is frankly daunting, if not utopian. Indications of surgery in MDR-TB remains to be a contentious issue, however, broad consensus is apparent now. Bacteriological cure in many series has been fairly impressive, with well over 90% success achieved with adjuvant surgery. Most such series are from the western world.[14, 15]

Hemoptysis

Surgery is not immediately required in a case of hemoptysis caused by pulmonary tuberculosis. Massive recurrent hemoptysis is the only justified indication in this setting. Conservative measures like positioning the good lung up after localizing the site, antibiotics, rest and sedation are almost always successful in controlling lung bleeding and surgery can be planned on an elective basis. Very often, post tubercular cavities are colonized by aspergillus fungus (aspergilloma) resulting in recurrent hemoptysis (Fig. 170.2). There are interventional measures other than surgery, which have their selected role in appropriate situations responsible for hemoptysis (Table 170.4).

TABLE 170.4: Different surgical interventions used for control of hemoptysis

- Endotracheal intubation to secure airway, suctioning and bronchoscopy
- Endobronchial tamponade with Fogarty catheter
- Laser photocoagulation (Nd-YAG or argon)
- Endobronchial hemostatic agents
- Selective bronchial artery embolization
- Surgical resection

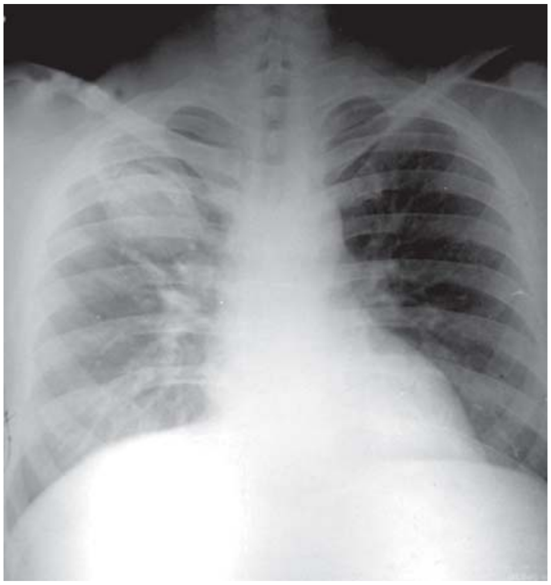

Fig. 170.2: X-ray chest of a patient with an aspergilloma in right upper lobe

Surgical resection of the involved portion of the lung is the most definitive and curative modality for treatment of massive and recurrent hemoptysis.[14] However in this technique, some points need to be emphasized. These include challenging surgeries involving careful dissection due to the presence of dense and unpredictable adhesions. A properly placed double lumen endotracheal tube, by which the anesthesiologist can collapse or inflate the lung depending upon the needs of the surgeon, is crucial. Position of this tube is confirmed with a pediatric fiber-optic bronchoscope and the time spent here is time well spent. This also protects the other healthy lung and ensures safety during surgery. The dissection of vascular structures at the hilum or in the fissure requires precise combination of sharp and blunt dissection. Adhesions are always a major challenge in this surgery. Use of a transfixation suture or double ligature on the proximal side while dividing arteries and veins is crucial to prevent deadly postoperative hemorrhage. Bronchus is closed with a bronchial stump stapler or with interrupted sutures. Equally good results have been shown by either of these techniques.

Empyema

Empyema continues to pose a challenge, and requires a common sense approach, for its management. The management depends upon the stage of presentation. Most of the cases are effectively managed with prolonged and expert intercostal tube management. In the subacute stage, drainage can be assisted by either vide-assisted thoracic debridement or instillation of intrapleural antifibrinolytic agents like streptokinase or urokinase. Decortication is indicated in the presence of persistent pleural infection in late fibrinopurulent stage. Thoracoplasty is partial decostalization of the thoracic cage to obliterate persistent pleural space. Whenever the lung is unlikely to expand due to an extensive disease or multiple bronchopleural fistulae, thoracoplasty is an appropriate intervention and is required quite often in our setting (Fig. 170.3). It is most suitable for management of postoperative empyemas. Results are quite gratifying.

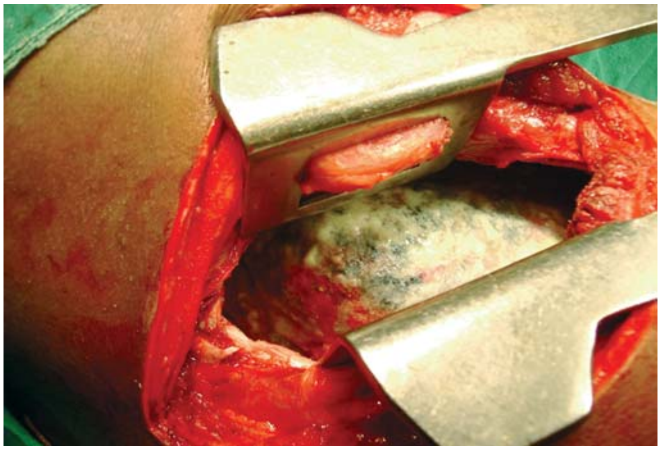

Fig. 170.3: Operative photograph of a case of tubercular empyema showing very little thickened pleura and diseased underlying lung—the reason why decortication is not suitable for most cases of tubercular empyema

Open Window Thoracostomy

Eloesser described a procedure to establish long-term open drainage of chronic empyema cavities in 1935. The procedure basically involves the creation of an open window thoracostomy in the chest wall for facilitating long-term open drainage without the need for an indwelling catheter. Various modifications of the procedure have been developed and described in the literature. It is an excellent procedure, the efficacy of which is matched by the beauty of its simplicity. Two to three ribs overlying the empyema cavity in the axillary region are partially resected, and the underlying pleura is stitched with the skin with the help of interrupted silk sutures. With good drainage being established, the empyema cavity slowly heals and closes over a period of months. Kohli and colleagues described complete expansion of the lung in 56% of 50 patients treated with open window thoracostomy over a period of 3 to 24 months after creating the flap.[16] A patient in the situation

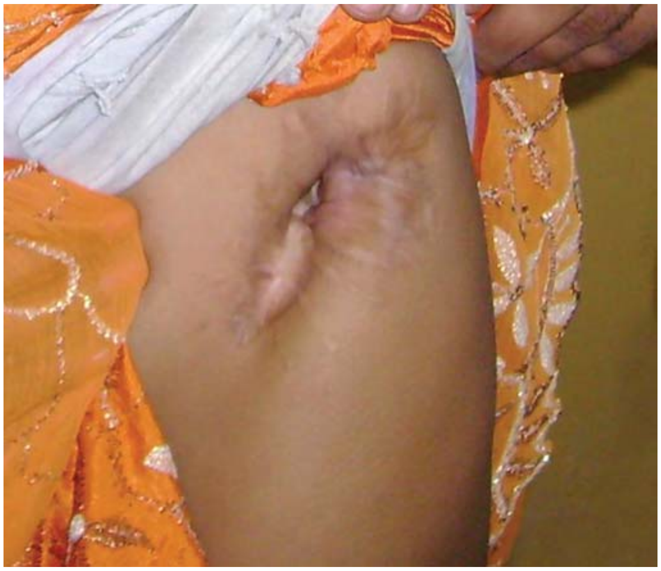

Fig. 170.4: Fully healed pleurocutaneous window, 8 months after the procedure

of chronic empyema, where the lung has not expanded after an adequate period of closed chest tube drainage and if the patient is judged to be not suitable for decortication because of diseased underlying lung, can be managed with this procedure. The results are generally excellent (Fig. 170.4).

Preoperative Work of a Thoracic Surgical Patient

There are some well-established prerequisites before a patient can be taken for surgery. It is of utmost importance that a detailed discussion is held with the patient and his relatives. This should include a frank talk about the natural course of the illness in the absence of any surgical intervention and the objectives of the proposed surgery in a given case. Risks of surgery and anesthesia are carefully explained along with the short-term and long-term results, if surgery is successful. It is of vital importance that a patient of pulmonary TB has taken an adequate course of ATT before the surgical decision is taken. Even an episode of massive hemoptysis as a presenting feature of pulmonary TB in a non-treated case is rarely an indication for surgical intervention. Patient's cardiorespiratory reserve to be able to withstand the surgery of this magnitude or proposed lung resection is carefully assessed. Various criteria have been laid down for different surgical indications and decision should be made jointly by the thoracic surgeons and the chest physician about the fitness of a given case after taking all the factors into account. Patients are urged to stop smoking for at least three weeks before surgery in order to ensure better postoperative results.

Postoperative physiotherapy, such as deep breathing, coughing and shoulder exercises, are taught to the patient in the preoperative period while forewarning him or her about a certain amount of expected postoperative pain. The patient should be as 'dry' as possible before surgery, meaning thereby that sputum or pus production (in cases of empyema) should be minimized by appropriate measures such as antibiotics, postural drainage, respiratory exercises, steam inhalation and nebulized bronchodilators, as appropriate. Some of these patients are quite weak and nutritionally depleted. Their nutritional status is built up before surgery, by rest and adequate diet, which may be sometimes ensured by hospitalization.

Bronchoscopy

Both rigid and fiberoptic bronchoscopies are excellent procedures and every thoracic surgeon should be able to perform them well. It is required for preoperative evaluation prior to all the surgical operations. Sometimes, bronchoscopy is also needed in the postoperative period to remove thick secretions or blood clots from the tracheobronchial tree.

Mediastinoscopy

It is required less often these days. However, mediastinal lymphadenopathy, which can be due to several diseases such as TB, sarcoidosis or lymphoma, is a perplexing clinical situation. If other measures fail to show a conclusive diagnosis, mediastinoscopy is a justified option for obtaining an adequate surgical biopsy.

Infective Conditions Other than Tuberculosis

Most of the indications and principles of surgery remain the same in all these conditions as for tuberculosis. Persistent septic foci in the lung or the pleura which do not resolve on medical management and remain a source of problems (like hemoptysis, empyema or other chest symptoms) warrant various kinds of surgical interventions, as described above. It may be mentioned that non-tubercular infective conditions generally do not cause significant lung destruction and hence the results of surgery are better. In cases of empyema of non-tubercular origin, good results can usually be obtained by intercostal tube management and decortication; open window thoracostomy and thoracoplasty are rarely required.

Postoperative Management

Results of surgery for TB and inflammatory lung disease improve if attention is given to detail in the postoperative period. Initial management is ideally done in an Intensive Care Unit (ICU). Antibiotics and painkillers are routinely given. Blood is transfused as per requirements. Respiratory exercises are encouraged and all measures to relieve pain should be taken. Incentive spirometry is a useful tool to achieve these aims. Care of the chest tubes is an essential ingredient of this management; these should be removed only when their output has completely stopped. Persistent air leak, development of bronchopleural fistula and residual pleural space are the most important issues to be carefully watched for, especially in the third postoperative week and onwards. These complications may require various kinds of intervention, including the open window thoracostomy and/or thoracoplasty.

Outcome of Surgery

Recent published series have demonstrated mortality of surgical interventions ranging from 0 to 3.1%.[17-21] The morbidity reported in most other series ranges from 3 to 53.7%. Postoperative empyema and BPF are best managed by prolonged tube drainage followed by open-window thoracostomy and thoracoplasty, if required. In the recent times, the use of good cardiac monitors, anesthesia support, pediatric fiberoptic bronchoscope to secure correct placement of the double-lumen endotracheal tube, liberal use of electrocautery, staplers for bronchial stump closure and adequate postoperative pain relief with epidural catheters have improved the results to the most optimum level. In the reported series, the operative aspects have been well addressed. Yet several issues such as the stapling versus suture techniques for lung and bronchus, air leak management and residual space problems need further debate and clarification. Pain relief, rehabilitation and long-term performance criteria are rarely discussed. All these issues require continued commitment from all the stakeholders to improve the results of this highly complicated and complex set of surgical patients.[22]

Surgery for inflammatory lung conditions like tuberculosis, whenever required, poses very special challenges. However, with adequate preparation, good case selection and optimal intraoperative and postoperative care, highly gratifying results can be achieved.

Surgical Aspects of Obstructive Lung Diseases

Donald Ray Lazarus, Suryakanta Velamuri

INTRODUCTION

Obstructive lung diseases are characterized by airflow limitation which may be reversible or irreversible. The common obstructive lung diseases include asthma, Chronic Obstructive Pulmonary Disease (COPD) (both chronic bronchitis and emphysema), and bronchiectasis. The primary treatments for obstructive lung diseases are pharmacologic therapies, most notably bronchodilators and inhaled corticosteroids. Non-pharmacologic methods such as smoking cessation are important adjuncts.

Surgery has little to offer a patient with chronic bronchitis in the absence of emphysema. Aside from local resection for patients with focal disease, surgical treatment of bronchiectasis is largely limited to lung transplant, which is covered elsewhere in this text. Surgical techniques used to treat emphysema and asthma have been described, but not as commonly used, as widely available, and have benefits that are often not as clearly defined as commonly used medical therapies. The aim of this section is to describe currently used, investigational surgical and procedural treatments for emphysema and asthma to include both proposed indications and possible benefits.

LUNG VOLUME REDUCTION SURGERY

Emphysema is characterized pathologically by the permanent enlargement of air spaces distal to the terminal bronchioles with destruction of the alveolar walls.[1] In addition to impairment in gas exchange, this pattern of tissue destruction leads to a loss of elastic recoil and an increase in lung compliance. These in turn cause spirometric changes with increases in Total Lung Capacity (TLC), Functional Residual Capacity (FRC) and Residual Volume (RV), and a decrease in Vital Capacity (VC).[1] These pathophysiologic changes underlie the rationale for Lung Volume Reduction Surgery (LVRS) in patients with emphysema.

Lung volume reduction surgery for emphysema was originally described in the 1950s by Brantigan and colleagues. While a substantial proportion of their patients reported symptomatic improvement, the reported operative mortality of 18% in the absence of objective measures documenting benefit prevented LVRS from becoming commonly used.[2] In the 1990s, Cooper and colleagues revisited surgical lung volume reduction using more modern surgical techniques, including the utilization of bovine pericardium to minimize persistent postoperative air leaks.[3] Their initial successes and those reported by several others in small case series eventually led to the National Emphysema Treatment Trial (NETT), a randomized trial designed to prospectively evaluate LVRS patients with emphysema.[2] This trial and its offshoots have given us the best evidence to date on the indications and effectiveness of LVRS and will be referenced extensively throughout this section.

While the reasons for improvements in pulmonary mechanics and symptoms after LVRS are not definitively known, several mechanisms for the clinical and physiologic improvements seen after LVRS have been postulated. Removing portions of hyperinflated lungs should improve elastic recoil and increase air flow by decreasing the size mismatch between the hyperinflated lungs and the chest.[4,5] Reducing lung volume may also increase diaphragm curvature and length, leading to improvements in diaphragm strength.[6] Decreases in intrathoracic volume after LVRS may improve left ventricular diastolic function.[7] LVRS may also lower the central respiratory drive and ventilatory response to CO_2.[8]

Patient Selection and Prediction of Outcomes

In addition to standard preoperative risk assessment, patients who are candidates for LVRS should be assessed preoperatively using both physiologic and radiographic studies in order to predict the likely benefit of LVRS and also to identify those patients who are at high risk of poor postoperative outcomes. Physiologic assessment most often involves pulmonary function testing with spirometry, lung volumes, and Diffusion Lung Capacity of Carbon Monoxide (DLCO). Exercise capacity is also evaluated. Measurement of inspiratory lung resistance by esophageal balloon is less commonly performed. Preoperative radiographic evaluation typically includes chest radiographs as well as a Computed Tomography (CT) scan of the chest.[9]

Physiologic variables that have been shown to predict physiologic improvement after LVRS include measured inspiratory lung resistance and the ratio of Residual Volume to Total Lung Capacity (RV/TLC). Preoperative inspiratory lung resistance as measured with an esophageal balloon correlated inversely with postoperative improvement in Forced Expiratory Volume in one second (FEV_1).[10] This technique is not commonly available in the clinical setting, which may limit its utility. Fessler and colleagues later showed that the RV/TLC ratio correlated with improved Forced Vital Capacity (FVC) after LVRS.[11]

Radiographic criteria have also been shown to independently predict outcomes in LVRS. In one study, the presence of bilateral upper lobe pattern of heterogeneous pattern of emphysema was the only examined factor that was strongly associated with a good clinical outcome.[12] Correlation with postoperative improvement and upper lobe predominant-emphysema, presence of compressed lung, and percentage of normal or mildly emphysematous lung as assessed by CT was reported.[13]

While previous small randomized trials have shown improvement in physiologic parameters and symptoms after LVRS, they were not powered to detect differences in mortality.[14,15] The National Emphysema Treatment Trial (NETT), which began enrolling patients in 1998, is the largest controlled trial examining LVRS. It found that a combination of physiologic, clinical, and radiographic factors could be used to determine which patients were most likely to receive significant benefit or suffer serious harm from surgery. A total of 1218 patients with emphysema and severe airflow obstruction (defined as FEV_1 less than or equal to 45 percent of the predicted value) were enrolled. After initial screening, they were randomized to receive either LVRS or medical therapy. All patients underwent an initial period of pulmonary rehabilitation as well. Numerous prespecified substudies were also performed.[2] Interim analysis of the first 1033 patients enrolled in the NETT identified a group of patients at very high-risk of mortality after LVRS (Table 171.1). Patients who had FEV_1 less than 20 percent of the predicted value and either DLCO less than 20 percent of the predicted value or homogeneous distribution of emphysema on CT had a mortality of 16 percent at 30 days, as compared to no deaths in the medically treated group. Only 28 percent of the patients in this high-risk group reported improvement in health-related quality of life. Based on this initial data, NETT stopped enrolling patients in this high-risk group.[16]

TABLE 171.1: Predictors of mortality after LVRS

FEV_1 less than 20% predicted
and either
Homogeneous or non-upper lobe predominant emphysema
or
DLCO less than 20% predicted

Based on data from reference 16

The NETT investigators subsequently published results from the remaining 1078 patients who did not fall into the high-risk group described above. Overall, mortality at 90 days was higher in the surgical group than in the medical group (5.2 vs. 1.5%), equal between the two groups over the short-term (mean 29 months, RR 0.89, p-value 0.31), and lower in the surgical group than the medical group in the long-term(mean 4.3 years, RR 0.86, p-value 0.02).[17,18] PaO_2 was also significantly better in patients who were randomized to LVRS versus medical therapy at 24 months[19], and COPD exacerbations were less frequent.[20] A substudy of the NETT evaluated the change in exercise capacity in 238 patients. It found that exercise capacity was better in patients who had LVRS along with improvements in respiratory mechanics and dyspnea.[21]

Subgroup analysis of the non-high risk patients identified four subsets of patients who had differing outcomes after LVRS. The best outcomes after LVRS were obtained in patients who had both upper lobe predominant emphysema and low baseline exercise

TABLE 171.2: Predictors of benefit from LVRS

FEV_1 less than or equal to 45% predicted
Upper lobe predominant emphysema
Exercise capacity less than 40 watts (men) or 25 watts (women)

Based on data from references 2,17,18

capacity (defined as less than the sex-specific 40th percentile) (Table 171.2). These patients showed no difference in mortality between the surgical and medical groups at 90 days, and decreased short-term and long-term mortality. This group also was more likely to have improvement in exercise capacity and to report improvement in health-related quality of life.[17,18]

The second subgroup of patients had upper lobe predominant emphysema and high baseline exercise capacity. LVRS did not alter mortality in this group at 90 days or in the short-term and long-term analyses. Surgery did improve exercise capacity and health-related quality of life, these improvements were sustained at four years after randomization.[17,18]

The third subgroup of patients had non-upper lobe predominant emphysema and low baseline exercise capacity. Within this subgroup, patients who underwent LVRS had an increase in 90 day mortality but no significant difference in short-term or long-term mortality when compared to medically treated patients, and there was no significant improvement in exercise capacity with surgery in this subgroup. Surgery did produce a statistically significant improvement in health-related quality of life at 12 months, but this effect was no longer present at three years.[17,18]

The final subgroup had non-upper lobe predominant emphysema and high baseline exercise capacity. Surgery resulted in increases in 90-day and short-term mortality without a significant difference in long-term mortality. There were no significant differences in exercise capacity and health-related quality of life between patients who received surgery and those who were treated medically in this subgroup.[17,18]

Surgical Technique

While a complete discussion of surgical technique is beyond the scope of this section, a brief description of relevant developments in surgical techniques related to LVRS will be relevant. Cooper and colleagues revived LVRS in the 1990s using a technique of stapled excision with the staple line buttressed by bovine pericardium to reduce air leaks.[3] Since then, other techniques have also been investigated, most notably laser coagulation, which McKenna and associates compared to staple excision in a randomized controlled trial containing 71 patients. There were no significant differences between the groups in mortality, hospital length of stay, or air leak beyond seven days. The group undergoing staple excision had a significantly greater improvement in FEV_1 postoperatively as well as a higher probability of having no need for supplemental oxygen postoperatively as compared with the group treated with neodymium:yttrium aluminum garnet (Nd: YAG) contact laser surgery. Patients treated with laser surgery also had a significantly increased rate of delayed pneumothorax.[22]

Postoperative outcomes for both staple excision and laser volume reduction techniques are similar. Staple excision is the preferred technique, and there appears to be no benefit gained by adding laser to staple excision.[23-25] The staple line is frequently buttressed to reduce the occurrence of prolonged postoperative air leaks. Bovine pericardium has been used most commonly as buttressing material, but bovine collagen was equivalent in one trial and may be less expensive.[26]

Median sternotomy remains the most commonly utilized surgical approach, although Video Assisted Thoracoscopic Surgery (VATS) is also commonly used. Some experts suggest that VATS is superior for patients with apical or posterior adhesions, and for patients with posterior bullae.[22] Kotloff examined 120 patients undergoing LVRS, 40 via VATS and 80 via median sternotomy. He found similar outcomes in the two groups with the exception of a higher rate of postoperative respiratory failure in the patients undergoing median sternotomy.[27] One NETT substudy compared outcomes in patients undergoing LVRS via median sternotomy vs VATS. No difference in mortality, morbidity, or functional outcome was found between the groups except for a slightly longer length of ICU stay and higher cost associated with median sternotomy.[28] No consensus exists as to the preferred approach.

In summary, lung volume reduction surgery is an effective treatment for carefully selected patients with severe emphysema. It has been demonstrated to improve mortality, exercise capacity, and quality of life in patients with upper lobe predominant emphysema and low exercise capacity. Patients with upper lobe predominant emphysema and high baseline exercise capacity do not derive mortality benefit from LVRS, but may gain some symptomatic benefit. LVRS cannot be broadly recommended for these patients, but they can be considered for surgery on an individual basis if dyspnea is severe. LVRS has not demonstrated mortality benefit or significant durable symptomatic benefit in those patients with non-upper lobe predominant emphysema and low baseline exercise capacity and so is not recommended in this patient population. Patients who fall into the high-risk group described above (FEV$_1$ less than 20% predicted and DLCO less than 20% predicted or homogeneous emphysema) or who have emphysema which is not upper lobe predominant with high baseline exercise capacity have excess mortality from LVRS and should not undergo surgery.

Bronchoscopic Lung Volume Reduction

Despite successful outcomes in selected patients with severe emphysema, lung volume reduction surgery is a major procedure associated with a significant perioperative morbidity and mortality. For this reason, several bronchoscopic techniques intended to collapse areas of emphysematous lung without the need for median sternotomy or thoracotomy have been explored. This may provide many of the benefits of LVRS without the same degree of perioperative risk. Lung Volume Reduction (LVR) should be theoretically possible if the conducting airways to emphysematous areas of lung were blocked or closed endoscopically, causing the alveoli distal to the blockage to collapse. Several methods which may accomplish this are being examined, although none have been fully studied to date.[29]

Ingenito and colleagues initially reported bronchoscopic LVR (also called biological LVR) using a washout solution to collapse segments of emphysematous lung followed by sealing and scarring the collapsed segments with a fibrin-based sealant in sheep.[30] Reilly and associates subsequently published a small phase 1 trial evaluating the safety of this method in humans by treating two or four emphysematous lung subsegments in a total of six patients. No significant adverse effects were noted, but larger randomized trials are needed to confirm the safety and efficacy of this procedure.[31] Endobronchial plugs and blockers have also been described in preclinical studies, but no human trials of safety or efficacy have been published.[29] Several groups of researchers are investigating the use of endobronchial one-way valves that can be deployed bronchoscopially using at least two separate proprietary valves. An advantage of an endobronchial valve over an endobronchial blocker is the ability to clear secretions through the valve while still maintaining volume reduction. All published trials to date are unrandomized and open label. Initial results suggest promising improvement in symptoms and in some spirometric parameters, with generally acceptable rates of complications.[32-36]

Another method which remains in the early stages of investigation is bronchial fenestration with airway bypass. The rationale for this technique is based on the observation that patients with emphysema have elevated dynamic resistance in the small airways. This is accompanied by increases in collateral ventilation. If a direct connection between the bronchus and the collaterally ventilated lung can be made, the airway segments with high resistance can be bypassed, improving ventilation and reducing airway resistance.[29] The procedure itself involves using a radiofrequency ablation catheter to create fenestrations in the bronchial walls at the segmental or subsegmental levels. Then expandable stents are placed that connect the bronchus to the lung parenchyma.[37,38] To date results have only been published outlining the feasibility of the procedure in excised emphysematous human lungs.[37] The degree and duration of clinical benefit to be gained from this procedure remain unknown, as do the long term risks.[29] Clinical trials of all of these procedures are ongoing, and the future role of these bronchoscopic LVR techniques is not yet clear.

Bullectomy for Giant Bullous Emphysema

Bullae are defined as distended air spaces greater than one cm in diameter.[39] Giant bullous emphysema is a relatively uncommon form of emphysema. Patients who have bullous emphysema often develop progressive enlargement of bullae, worsening airway obstruction, and worsening dyspnea. Even with optimal medical therapy, dyspnea and severe obstruction can be very limiting for patients with giant bullous emphysema.[1] Spontaneous pneumothorax, often recurrent, is also reported, and bullectomy can be effective at preventing recurrence.[40] Resection of giant bullae in selected patients can result in reduction in airway resistance, improvement in elastic recoil, and a decrease in functional residual capacity. Dyspnea can also improve. Resection of bullae does not appear to cause those remaining to increase in size, and bullae do not typically recur after resection.[41] Reported operative mortality rates are between 0 to 22.5% in most case series, with a mean weighted mortality of around 8%. Durable improvement in symptoms and function can be expected in 60 to 90% of appropriately selected patients.[39]

Patient Selection and Prediction of Outcome

Even patients with severe emphysema do not commonly have bullae large enough that bullectomy would be beneficial. Careful preoperative evaluation and patient selection can identify the patients who are most likely to derive benefit from surgery and exclude those who are likely to have excessive morbidity or mortality. Typical preoperative assessment of a patient being considered for bullectomy includes chest radiographs and CT of the chest as well as spirometry with lung volumes and DLCO. Indications for bullectomy include the presentation of progressive dyspnoea and bullae occupying 30% or more of the hemithorax (Table 171.3).

Radiographic studies and physiologic tests can be used to predict the likelihood of improvement after bullectomy. In a series of forty six patients undergoing bullectomy for bullous emphysema, those who had bullae occupying more than one-third of the hemithorax had a significant increase in FEV_1 and FVC and concomitant decrease in TLC and RV at five years after bullectomy. While patients with bullae occupying less than one-third of the hemithorax also had reductions in TLC and RV, they did not demonstrate the improvements in airflow seen in patients with larger bullae.[40] Results of pulmonary function tests can also predict the likelihood of good outcome after bullectomy. The slope of the third phase of the single breath nitrogen washout curve and FEV_1 were shown to correlate with postoperative performance status in patients undergoing bullectomy. Third phase slope less than 5% and FEV_1 greater than 50% of the predicted value have better postoperative performance status.[42] Conversely, FEV_1 less than 500 mL and hypercapnia have been shown to predict poor prognosis, therefore, constitute a contraindication to bullectomy (Table 171.4).[43] Right ventricular hypertrophy and cor pulmonale also predict poor outcome.[41]

Several recent case series have examined physiologic and clinical outcomes after giant bullectomy. Schipper and colleagues evaluated 43 patients who underwent surgery for giant emphysematous bullae between 1994 and 2002 with mean follow up of over four years.[44] FEV_1 and DLCO were significantly improved over preoperative values at six months after surgery, and this improvement was sustained at three years. RV was significantly decreased at six months after surgery, and this improvement was maintained for two years. Improvement in six-minute walk distance was present out to one year postoperatively. Perhaps most importantly, dyspnea scores and quality of life measures improved significantly postoperatively, and these improvements were still present at three years postoperatively. The most common complication was prolonged air leak, which was present in 53% of patients. Mortality was low, at 2.3%.[44]

TABLE 171.3: Indications for bullectomy
Progressive dyspnea
Bullae occupying 30% or more of the hemithorax
FEV_1 greater than or equal to 50% predicted
OR
Large bullae and history of spontaneous pneumothorax ipsilateral to bullae

TABLE 171.4: Contraindications to bullectomy
FEV_1 less than 500 mL
Hypercapnea (relative contraindication)
Pulmonary hypertension with right heart failure

Another group prospectively identified 41 consecutive patients undergoing bullectomy and followed them with periodic clinical and physiologic evaluation for five years.[45] Dyspnea decreased markedly, continued to decrease through four years of follow up, and remained below the preoperative baseline level of dyspnea through the fifth year of follow up. FEV_1 also improved postoperatively and was still significantly better than the preoperative baseline through the fifth year of follow up, and resected bullae did not recur. Operative mortality was 7.3%, well within historical norms for bullectomy.[45] Neviere and associates prospectively evaluated pulmonary function, exercise testing, and dyspnea in 12 patients who underwent bullectomy. They observed significant improvements in FEV_1, DLCO, dyspnea score, and exercise capacity after bullectomy. These all remained significantly better than the preoperative baseline throughout the four year follow up period. All patients survived.[46]

Surgical Technique

A variety of surgical approaches are used to accomplish bullectomy, and no consensus exists as to the superiority of any one approach. For bilateral bullectomy, median sternotomy is typically used, but lateral thoracotomy may be preferred for unilateral procedures. Video assisted thoracoscopy is also used somewhat less often.[44-46] Multiple methods can also be used to excise the bulla. The most common are simple placation, stapler excision, and laser ablation. No controlled trials to date have compared the various methods.

Bullous emphysema is associated with progressive dyspnea and airflow obstruction. Resection of giant bullae has been demonstrated to be beneficial in reducing dyspnea and airflow obstruction in carefully selected patients. It is also indicated for patients with bullous emphysema and history of spontaneous pneumothorax. Multiple surgical techniques are used. Those patients with emphysematous bullae occupying greater than one-third of the hemithorax and who have FEV_1 greater than 50% predicted are likely to benefit from bullectomy. Those with smaller bullae or FEV_1 less than 40% predicted or 500 mL, significant hypercapnea, or right heart failure have excess operative mortality, so surgery should be avoided in these patients.

Bronchial Thermoplasty for Asthma

One of the hallmarks of asthma is airway hyperresponsiveness with bronchoconstriction. Despite the use of both antiinflammatory agents and bronchodilators, many patients with asthma continue to have recurrent exacerbations. Whatever the inciting event, bronchoconstriction results from contraction of smooth muscle in the bronchial walls. It has also been demonstrated that patients with chronic, poorly controlled asthma often have airway remodeling, hyperplasia of smooth muscle in the airway walls is an important component of this remodeling. It has, therefore, been postulated that by reducing the ability of airway smooth muscle to contract, the frequency of asthma exacerbations in patients who have been refractory to standard pharmacotherapy might be reduced. This constitutes the rationale underlying the investigational therapy for asthma called bronchial thermoplasty, although the full mechanism by which it works, remains unknown.[47,48]

The procedure itself involves the bronchoscopic access of the airways followed by deployment of an expandable basket with four electrode arms. These electrodes contact the airway walls, and the heat generated by radiofrequency energy is used to disrupt the epithelium at the points of contact. The technique can be used in the airways of three millimeters in size, or larger.[47] Initial studies in the canines indicate that the areas which are treated, fully re-epithelialize later with the exception of airway smooth muscle, which is replaced by loose connective tissue. In initial studies on dogs this had resulted in decreased airway constriction in response to methacholine up to three years after treatment. No stricture formation, generalized airway fibrosis, or mucus plugging were observed.[49] These promising results in animals have since led to trials in humans, some of which have been summarized here.

Evidence from Clinical Trials

Cox and associates evaluated sixteen patients with stable asthma in a nonrandomized prospective study to assess the safety of bronchial thermoplasty. All subjects underwent baseline spirometric evaluation as well as spirometry on the day of each treatment. The subjects were also given systemic corticosteroids around the time of treatment. The participants then underwent bronchial thermoplasty in three or four separate sessions, with all lobes treated except the right middle lobe. Treatments sessions were separated by three weeks, and patients were followed for two years after completing the treatments. The procedure was well tolerated, with 84% of procedure-related adverse events rated as mild, with the remainder classified as moderate. No severe adverse events or deaths were reported. All adverse events, occurred in the week after treatment, mostly cough, dyspnea, wheeze, and bronchospasm appeared to be related to airway irritation.[50]

The Asthma Intervention Research (AIR) trial was conducted to assess the affects of bronchial thermoplasty on asthma control. This multicenter randomized controlled trial enrolled 112 patients with asthma classified as moderate or severe persistent and who were taking daily Inhaled Corticosteroids (ICS) and Long-Acting Beta Agonists (LABA). Subjects also had to have objective evidence of airflow obstruction, positive methacholine challenge test for airway hyper-responsiveness, stable asthma (defined as unchanged use of asthma maintenance medication and rescue medication), and worsening of symptoms or peak flow during a required two week trial of abstention from LABA use prior to randomization. Patients were randomized to treatment and control groups. The control group was treated with ICS and LABA. The study was nonblinded, and no sham procedures were performed. The treatment group received bronchial thermoplasty in addition to continuing treatment with ICS and LABA. Bronchial thermoplasty was performed in the treatment group in three separate treatment sessions separated by approximately three weeks. Subjects were assessed at 3, 6, and 12 months after the last study treatment during a two weeks period in which LABA was withdrawn. The bronchial thermoplasty group showed a greater decrease in rate of mild exacerbations from baseline at 3 and 12 months after treatment than the control group. There was no difference at six months. There was no difference in the rate of severe exacerbations between the treatment and control groups. Patients in the bronchial thermoplasty group had a higher rate of adverse events, primarily exacerbations of asthma occurring in the first week after treatment. No change in FEV1 was shown. Post-hoc analysis suggested the greatest benefit was obtained by those patients who were on the highest doses of ICS at baseline.[51]

Pavord and associates performed a nonblinded randomized trial of 34 patients with severe, symptomatic asthma to evaluate the safety and efficacy of bronchial thermoplasty in this patient group. They included patients with asthma who were on high dose ICS as well as LABA, demonstrated airway hyperresponsiveness or reversible bronchoconstriction, and symptoms despite maintenance therapy. A significant number of patients were also on systemic corticosteroids as well. Patients in the bronchial thermoplasty group had a higher rate of adverse events in the treatment period, with most of these related to worsening asthma symptoms occurring within a day after the procedure and resolving within a week. Two patients experienced lobar collapse within two days of bronchial thermoplasty, and one required bronchoscopy with removal of a mucus plug to re-expand the affected area of lung. In both cases the collapsed portion of lung was the most recently treated lobe. During the post-treatment period there were no significant differences in adverse events. The group receiving bronchial thermoplasty had significantly greater reductions than the control group in the use of rescue inhalers and significantly greater improvements in the Asthma Control Questionnaire and the Asthma Quality of Life Questionnaire at 22 and 52 weeks. The treatment group also had a significantly greater improvement in prebronchodilator FEV_1 at 22 weeks, but this difference was not sustained to 52 weeks.[52]

More recently, the AIR2 trial sought to evaluate bronchial thermoplasty for patients with symptomatic severe asthma in a blinded prospective randomized trial. The investigators randomized 288 patients who were on high dose ICS and LABA for asthma. Patients also had to have been on stable doses of asthma maintenance medication for four weeks prior to entry, have Asthma Quality of Life Questionnaire (AQLQ) scores less than 6.25, prebronchodilator FEV1 greater than or equal to 60% of the predicted value, evidence of airway hyperresponsiveness, and have had at least two days of asthma symptoms in the four-week baseline period. All subjects underwent three bronchoscopies at three week intervals. The results did indicate a greater change from baseline in AQLQ scores in the bronchial thermoplasty group, but the difference was not large. There were no significant changes in FEV1 or total symptom score. Both groups experienced a significant number of adverse events during the treatment period, with the bronchial thermoplasty group reporting more events, and also more serious adverse events. The most common adverse events were typical of airway inflammation, but 16 patients in the thermoplasty group required 19 hospitalizations compared to only two subjects in the sham group who needed two hospitalizations. During the post treatment period, the treatment group had a lower rate of emergency room visits and hospitalizations, but the number of emergency room visits and hospitalizations for respiratory events over the course of the entire study was no different between the groups.[53]

CONCLUSION

New and promising surgical interventions for both emphysema and asthma are being discussed. The field continues to evolve, particularly with regard to minimally invasive bronchoscopic methods. Bronchial thermoplasty shows promise as an adjunct treatment in patients with severe asthma who remain symptomatic despite optimal medical treatment. In addition to expense, it is limited by the need for multiple invasive procedures with a significant rate of adverse effects. Its role needs further elucidation before it can be recommended for widespread use. It is hoped that further assessment of their outcomes will justify the optimism that currently exists.

Thoracic Trauma

RS Dhaliwal, Bhalinder Dhaliwal

INTRODUCTION

Trauma is the leading cause of death, hospitalization and long-term disability for all the age groups from infancy to the old age. The earliest recorded reference to thoracic trauma is found in the "Edwin Smith Surgical Papyrus" written around 3000 BC. Much later, the closed chest tube drainage system, developed between the period of World War I and II in the 20th century had made marked impact on the treatment and outcome of chest injuries. Also during the World War II, thoracotomy became the most effective method to drain clotted hemothorax and to remove peel from the lung in case of empyema.

In multisystem trauma, chest-injury ranks third, after head injury and extremity (limb) fractures. Chest-injury is the cause of death in 25% of all deaths due to trauma.[1] Respiratory problems following chest injuries contribute significantly to 75% of deaths due to trauma. Blunt chest trauma is fatal in about 10% of cases, rises to 50%, if there are associated head and orthopedic injuries or abdominal trauma.[1]

In India, several factors such as the population explosion, marked increase in the number of vehicles, poorly regulated traffic control, driving under the influence of alcohol and drugs, and passion for speed are responsible for an alarming increase in the number of road traffic accidents. The situation is similar in several other developing countries. Road traffic accidents are the main causes of blunt chest and multi-system trauma. Increase in the domestic as well as the civilian violence due to activities of terrorism has lead to an increase in penetrating chest injuries caused by gun-shots, bomb blasts and stab injuries. Penetrating chest injuries have a mortality of 5% for simple stab-wounds to over 15% for gun-shot wounds. Less than 20% of patients with chest injuries require surgical intervention. Majority of chest injuries can be managed in small peripheral hospitals but a small number requires hospital admission and treatment in specialized cardiothoracic centers.[2]

The age of the patient plays an important role in the severity of an injury. In a pediatric patient, the chest wall is elastic and flexible, fractures are rare but intrathoracic injuries are common. In the elderly patients, the fragile bony thorax is highly susceptible to even the low impact-forces and offer poor protection to the underlying organs. Mortality is high even with minor injuries. Penetrating injuries are uncommon in both the elderly and the pediatric patients but they constitute the most common cause of death from trauma in persons of up to 50 years of age.

There is a desperate need of trauma-hospitals, rapid transportation of trauma-victims, improvement of road conditions, strict implementation of traffic-rules and knowledge of Cardiopulmonary Resuscitation (CPR) by paramedical persons and general public so that mortality and morbidity can be lowered in these patients.

PATHOPHYSIOLOGY[3]

The major visceral injury in chest trauma occurs due to three main mechanisms depending on the pattern of injury.

High Velocity Impact

This happens in high speed motor-vehicle collisions, when the chest wall suffers direct impact caused by rapid deceleration. The shearing force may cause transaction of bronchi or trachea, tear of the aorta and rupture of the diaphragm. There may be no or little injury to the chest wall, but the presence of bilateral-clavicular fractures or fractured-sternum should arouse suspicion for an internal organ injury. Anterior chest wall contusion may also be a warning for the underlying myocardial injury.

Low Velocity Impact

Low velocity force like direct blows to the chest wall cause damage to the bony cage with or without contusion of the underlying lung or myocardium. There may also be rupture of liver or spleen due to direct impact on the lower ribs.

Crush Injury

Crush injury may occur during industrial accidents, motor vehicular accidents and collapse of a building, where chest is crushed between two hard surfaces. Multiple bilateral rib fractures are common due to chest wall compression. The relatively low-velocity forces seldom damage the aorta or myocardium, but may rupture the diaphragm or lacerate the bronchi. The laceration is caused by widening of transverse diameter of chest-cage, pulling apart of the two lungs produces traction on the tracheobronchial tree.

EFFECTS ON LUNGS AND CHEST WALL

Chest injuries affect pulmonary functions adversely through three different mechanisms:

i. *Altered mechanics of respiration:* There is impairment of ventilation in majority of blunt and penetrating chest injuries that cause hemothorax and/or pneumothorax. Even simple rib fractures which cause sufficient pain may lead to hypoventilation, atelectasis, retained secretions, pneumonia, respiratory failure and septicemia in an elderly patient. More serious problems like tension pneumothorax, injury to major airways, multiple bilateral rib fractures with flail segment and ruptured diaphragm cause severe impairments in the mechanics of breathing. Multiple rib fractures may cause significant blood loss into chest wall and pleural cavity, which may further increase due to lung lacerations caused by sharp edges of the fractured ribs.

   There are two main types of chest wall derangements: A sucking chest wound and a flail segment. The flail segment is unstable, moves in during inspiration (paradoxical movement) and compromises ventilation by reducing the tidal volume. Following diaphragmatic rupture, the abdominal organs are sucked into the chest on inspiration causing lung collapse. If the pleural cavity is filled with air or blood, ventilation is compromised due to partial or complete collapse of lung. Injury of a major airway or inhalation of foreign material such as a loose tooth, stomach contents or road side debris may physically occlude the large (or small) airways leading to altered respiration.

ii. *Ventilation/perfusion imbalance:* Effective oxygenation of the blood and elimination of CO_2 depends on the fine balance between ventilation of the lung and its blood supply. Mechanical obstruction of the airway is an obvious cause of impaired ventilation, but in practice other mechanisms predominate. Normally, the inspired gases distribute preferentially to the areas of greater expansion which are the dependent portions of the lungs. If terminal alveoli are collapsed due to hemothorax or pneumothorax, inspiration results in preferential distribution of air to the already expanded areas. This maldistribution in the terminal airways due to external compression raises the intrapleural pressure. When a lobe or the whole lung collapses, there occurs a veno arterial shunt in the non-ventilated lung and systemic hypoxia results. Perfusion may be impaired due to thrombosis of vessels in the contused lung, due to fat embolism or platelet neutrophil microemboli in patients with Disseminated Intravascular Hemolysis (DIC) or ARDS.[4] Even a minor thoracic trauma may cause ventilation/perfusion imbalance causing severe hypoxia, recognized mainly by blood-gas analysis.

iii. *Impairment of gas transfer:* Passive diffusion of gases across the alveolar capillary membrane is dependent on the available surface area, the membrane-width, certain enzymatic factors and the partial pressure gradient between the alveolar and vascular compartments. In thoracic trauma, there is an adverse effect on gas exchange due to factors like pulmonary contusion, damage to the alveolar capillary membrane by inhalation of gastric contents or smoke, impaired cardiac output, interstitial pulmonary edema due to over transfusion of fluids or blood. The most serious process begins with the pathophysiological effects of shock. If unchecked, the condition progresses to Acute Respiratory Distress Syndrome (ARDS).[2] The mortality is quite high once

TABLE 172.1 Classification of chest injuries

Blunt Chest Injuries

1. Thoracic cage injuries
    - i. *Fracture Rib*
    - ii. *Flail Chest (multiple fracture ribs)*
    - iii. *First rib fracture*
    - iv. *Fracture of Sternum*
2. Injury to Pleura
    - i. Tension pneumothorax
    - ii. Open Pneumothorax
    - iii. Hemothorax
3. Surgical Emphysema
4. Lung parenchymal injury
5. Major airway injury
6. Diaphragm injury
7. Heart injuries
8. Rupture of aorta
9. Esophageal injury

Penetrating Chest Injuries

1. Pneumothorax / Hemothorax
2. Tension Pneumothorax
3. Pericardial tamponade
4. Cardiac injury
5. Tracheobronchial injury
6. Pulmonary parenchymal injury
7. Esophageal injuries
8. Great vessel injuries

ARDS occurs in a patient of thoracic trauma, especially after multiple injuries.

Classification (Table 172.1)

i. ***Blunt chest injury:*** It occurs mainly from automobile accidents; other causes being fall from height and crush-injury.

ii. ***Penetrating chest injury:*** In civilian violence, stab-injuries and low-velocity gun shots are the main causes. Marked increase in terrorism has introduced bomb-blasts and high-velocity guns-injuries which are far more damaging to the chest wall and the thoracic organs. In wars and military practice, high velocity missiles such as the gun shots and bomb blasts are the main cause of penetrating chest injuries.

BLUNT CHEST TRAUMA[2-4]

Thoracic structures get injured in varying degrees of severity in any combination. There may be little external evidence of the severity of the internal damage. If skeletal injuries are severe, the underlying parenchymal injuries are likely of the same proportion, except in the younger patients with flexible chest walls.

Patterns and Manifestations of Blunt Chest Injuries

Thoracic Cage Injuries

i. *Fracture rib* : This occurs mostly due to direct trauma. A simple rib fracture may be serious in the elderly individuals or in patients with chronic lung diseases with decreased pulmonary reserve. Chest X-ray is required to exclude pneumothorax. A routine chest X-ray may miss rib fractures. Uncomplicated fracture requires sufficient analgesia to encourage adequate ventilation and coughing. Oral analgesic drugs may suffice but intercostal nerve block with long acting local anesthetic drugs like bupivacaine may be helpful. Chest strapping is of little use, early ambulation and vigorous physiotherapy are encouraged. Oral antibiotics are required to prevent chest infection. Once pneumothorax and major internal organ injuries are excluded, the mainstay of management is control of local chest pain.

ii. *Flail chest*[5] *(Multiple fracture ribs):* Fracture of three or more ribs at two or more points, with or without associated fracture of sternum leads to flail chest. The flail-segment shows paradoxical movement, i.e. during inspiration, the chest is drawn inwards and on expiration it goes outwards, interfering with normal mechanism of respiration, resulting in hypoxia, atelectasis and hypercapnia. Associated pulmonary contusion aggravates the progressive respiratory failure.

If the segment is small which does not interfere with respiration and there are no associated major injuries, the patient should be observed in an Intensive Care Unit (ICU) with regular blood gas monitoring. Adequate analgesia and chest physiotherapy are required until the flail segment stabilizes. In a massive flail chest, the patient is ventilated for three to six weeks till the segment becomes less mobile or gets stabilized. Flail segment in itself is not an indication for assisted ventilation; it is the onset of respiratory failure due to the injury which necessitates ventilation. Thoracic epidural analgesia is also a good method in decreasing mortality in patients with multiple rib fractures without ventilatory support. The requirement for mechanical ventilation in patients with chest wall injury may reduce from 100 to 10% by epidural anesthesia.

Surgical fixation and chest wall stabilization are rarely done these days. Chest wall fixation may be done in case thoracotomy is required for excessive bleeding, laceration of lung or for clotted hemothorax. It may eliminate the need for ventilation in some patients and decrease the risk of pulmonary infection.

iii. *First rib fracture*[6]*:* It requires significant force to fracture the first rib which may be associated with injury to major neurovascular structures at the thoracic inlet. The mortality and morbidity are higher in patients of thoracic trauma having first rib fracture. Fractures of lower ribs can cause spleen-injury on the left side and liver-injury on the right side.

iv. *Fracture of sternum*[7]*:* Sternal fracture can occur due to sudden deceleration especially when driving fast. With seat belts in place, the steering wheel injuries are now much less common. The injury is quite painful even if only the external plate of the sternum is fractured. There is risk of an underlying myocardial damage, the patient should be observed in the hospital with Electrocardiogram (ECG) and cardiac enzyme monitoring. Most patients require only the analgesic drugs. If there is a marked paradoxical chest wall movement, it requires internal fixation of sternal segments by the wire or metal plates.

Injury to Pleura[8]

Injury to pleura may result in tension or open pneumothorax depending upon whether the visceral pleura is breached or a sucking chest wound is there. There may be associated hemothorax.

i. *Tension pneumothorax:* The injury to lung parenchyma which creates a flap valve mechanism allows air to enter the pleural cavity which can not get out during expiration via tracheobronchial tree or outside into the atmosphere. The air entrapment leads to the development of tension in the pleural cavity causing collapse of the lung and interference with the venous drainage to the heart. There occurs shift of mediastinum, and compression of large intrathoracic veins. Decreased cardiac output and sudden death can also happen.

The clinical diagnosis of tension pneumothorax can be made in a patient who had chest injury from the presence of marked respiratory effort, restlessness, cyanosis and dilated neck veins. Examination may reveal the presence of mediastinal shift, hyper-resonant note and absence of breath sounds on that affected side. Patient should not be sent for chest X-ray. The immediate treatment is required to release tension by insertion in the 5th intercostal space of an intercostal chest tube attached to an underwater seal.

ii. *Open pneumothorax:* It is more common in a penetrating chest injury. Usually, there is a wound in chest wall which is open to atmosphere, and it sucks air: "Sucking chest wound". Treatment consists of sealing of the sucking chest wound and an insertion of intercostal chest tube.

iii. *Hemothorax*[9]: In both blunt and penetrating injuries, the incidence of isolated hemothorax is 25 to 30%, in the remaining it may coexist with pneumothorax.

The pleural cavity has a potential capacity of 2 to 3 liters. On plain chest X-ray, a collection of up to 1 liter may be missed on a supine film. Slightly increased opacity of one lung field may be the only clue. A lateral decubitus film is useful to detect collection in the pleural cavity in a doubtful case.

In 80 to 90% of the cases, the source of bleeding is from the intercostal or the internal mammary arteries, pulmonary vessels are the source in 10 to 20% cases. Multiple rib fractures cause significant blood loss into the pleural cavity and the chest wall. Blood loss from lung lacerations is not much due to the low pulmonary pressure. In contrast, bleeding from aorta or big intrathoracic vessels is massive and usually fatal.

In majority of cases of hemothorax, insertion of a chest tube drain is the only required treatment. This encourages lung expansion which helps in arresting the bleeding. If hemothorax is neglected, it can lead to empyema and fibrothorax.

Surgical Emphysema

There is passage of air into the surrounding tissues when ever there is disruption of the respiratory tract at any level. Mediastinal emphysema occurs when air enters the mediastinum from a tracheobronchial tear or from perforation of the esophagus. The air moves inside the neck where it escapes from the deep tissue planes and enters the subcutaneous tissue. In case, the lung is stuck to the chest wall due to old tuberculosis or another infective lung disease, the injury to the lung parenchyma will lead to surgical emphysema, the lung does not collapse due to the adhesions with the chest wall and the air leaks into the subcutaneous tissue. Clinically, the patient's appearance is quite "distorted", but in most cases it does not require any treatment. More important is to treat the associated pneumothorax and to stop the air leakage.

Lung Parenchymal Injury[4]

Pulmonary contusion is caused by rapid deceleration against a steering wheel, fall from a height and from blast injuries. In young persons, there may not be any fracture of the ribs or sternum. There is capillary disruption causing intra-alveolar and interstitial hemorrhage, edema and obstruction of the alveoli and small bronchi by the exudates. Pulmonary contusion is often a part of a major chest injury that includes one or more fractures of ribs, pneumothorax and hemothorax. A large contusion may result in serious respiratory dysfunction. Pneumothorax or hemothorax can also develop later due to disruption of the contused pulmonary parenchyma.

Blood gas monitoring is important for treatment. A large number of patients with lung contusion require assisted ventilation for support. Continued hemorrhage and massive air leak require early thoracotomy and pulmonary resection, mortality is high in such cases. Small contusions usually resolve with physiotherapy, antibiotics and intercostal drainage.

Major Airway Injury[10]

Injuries to the major bronchi produce massive surgical emphysema, hemoptysis, pneumothorax and marked respiratory distress. Lung does not expand even after an intercostal chest tube when there is massive air leakage in the underwater seal bottle. Urgent thoracotomy and repair of the tear in the bronchi is needed. Lung resection is rarely required. Recovery is generally good after surgery.

Diaphragm Injury[11]

Injury to the diaphragm is more common on the left side, the right side is protected by liver. Tear is common on the posterolateral aspect. Abdominal contents such as the stomach, colon, and spleen may herniate into the chest, causing respiratory distress. Bowel sounds may be heard over the chest wall on the affected side. Chest X-ray in such a case may be confused with traumatic hemopneumothorax. Instances of perforation of stomach or colon with serious complications, while placing chest tube have been reported in these patients. Ryle's tube placement and chest X-ray examination are useful simple tests to diagnose this condition. Ultrsound, Computed Tomography (CT) scan and contrast study will confirm the diagnosis.

Cases missed during acute condition may present later with chronic diaphragmatic hernia. Patient coming in the acute stage should be explored by thoracotomy or laparotomy through thoracoabdominal incision. The abdominal organs are reduced back and the diaphragm is repaired after excluding/repairing injury to the liver, stomach or spleen.

Heart Injuries[12]

Major injuries to heart or great thoracic vessels are usually fatal, patient rarely reaches the hospital alive. Following types of injuries are generally encountered:

i. *Myocardial contusion*: Myocardial contusion is suspected, when sternum is fractured. The ECG pattern and enzyme changes are similar to those of myocardial infarction. Arrhythmias and cardiac failure are common. The patient should be kept under close observation in the ICU/Critical Care Unit (CCU) with full monitoring and resuscitation facilities being available. The risk of fatal arrhythmia decreases once enzymes and the ECG pattern become normal.

ii. *Heart chamber, valve or septum injury*: Rupture of a cardiac chamber is usually fatal, those who reach hospital alive are having small atrial or ventricular injury. Clinical picture is usually that of cardiac tamponade. Rupture of a cardiac valve or septum suspected from the presence of a loud murmur over the precordium causes heart failure. Open heart surgery is usually required for valvular or septal injury. Chamber-injury can sometime be repaired with a closed procedure, with standby heart lung machine. Results are dramatic in these very serious patients.

Rupture of Aorta[13]

About 15 to 20% of patients who die in the automobile accidents have some form of aortic injury. Aortic transaction is usually due to major deceleration force. Only 15% patients with aortic transaction survive long enough to reach the hospital alive. Of them, two-third will die of late rupture within two weeks and the remaining can develop false aneurysm. The most common location of this injury is just distal to the origin of the left subclavian artery. The classical finding in aortic transaction is the presence of normal or elevated B.P. in the right arm and low or absent B.P. in lower limbs. There may be radiofemoral pulse delay, infrascapular pain and an audible murmur at the back. Urine flow is decreased or absent. Patient may be completely asymptomatic. Chest X-ray is quite diagnostic in aortic transaction. CT scan is not of much help. Aortography is the confirmatory investigation of choice. Once the diagnosis is confirmed, immediate surgery should be undertaken. Left thoracotomy through 4th intercostal space is done. After proximal and distal control of aorta, the tear is repaired by direct suturing or interposition graft. There is risk of paraplegia after aorta is cross clamped, so some kind of aortic bypass shunt or atrio-femoral bypass should be used for spinal cord protection.

Esophageal Injuries

Esophagus is rarely injured in blunt chest trauma. The usual mode of esophageal injury is through endoscopy and esophageal intervention procedures.

PENETRATING CHEST INJURIES (PCI)[14,15]

The primary injury produces an open communication between the intrathoracic contents and the atmosphere. When examining the patient, the mode of PCI should be established, such as the position, the direction of entry and exit and the size of the wound to know about the intrathoracic organ injured.

The injury may be central or peripheral. The central area is bound superiorly by the sternal notch and clavicles, laterally by the midclavicular lines and inferiorly by the costal margin and the xiphisternum. Peripheral injuries lie on either side of these boundaries. The central and peripheral regions are further subdivided into superior and inferior regions by a line joining the two nipples. The path of the penetrating object can extend from central to peripheral areas and vice versa. Centrally located injuries are likely to be more serious since they involve the mediastinal structures. Chest injury below the level of diaphragm may extend into the liver, stomach and spleen.

Patterns and Manifestations of Penetrating Injuries

Pneumothorax/Hemothorax

Co-existing pneumothorax and hemothorax are the most common complications of PCI. Sucking wounds with size of more than two-third of tracheal diameter are hazardous since the air will enter the wound and into the pleural cavity more than it enters in the trachea. An open chest wound which is larger than laryngeal cross section area, will cause lung collapse, shifting of mediastinum, hypoventilation and reduced cardiac output. Sealing of the wound by dressing and placing an intercostal chest tube should be urgently done, followed by suturing of the wound or chest wall reconstruction.

Tension Pneumothorax

Diagnosis and management of the conditions due to PCI are similar to that of the blunt chest injuries.

Pericardial Tamponade

Tamponade is one of the major complications of PCI involving the central area. There is significant hemopericardium causing interference with the filling of the heart during diastole and a fall in the cardiac output. Classical signs of Beck’s triad are seen in 40% cases. Pulsus paradoxus may be present. Chest X-ray may show globular heart. The 2-D echocardiography has 96% accuracy, 90% sensitivity and 97% specificity for the diagnosis of cardiac tamponade in PCI. Unstable patient may require emergency thoracotomy. Diagnostic pericardiocentesis has a 33% false negative or false positive result due to the presence of clotted blood. Subxiphoid pericardiotomy as a diagnostic and therapeutic technique has been recommended by many authors. These should be done in the operation theater where facilities for immediate thoracotomy or midsternotomy are available since the release of tamponade may be followed by massive bleeding from the heart.

Cardiac Injury[15]

About 15 to 20% patients with cardiac injury may reach the hospital alive depending on the type of PCI, speed of the transport to the hospital and an early implementation of life support measures. Right ventricle, right atrium and left ventricle are the more common sites of cardiac injuries. Injuries to the valves, septum and coronary arteries are less common. Between the tamponade and frank hemorrhage, the former carries better prognosis than latter. Midsternotomy or left anterolateral thoracotomy is the common approach for cardiac injuries. Small tears can be controlled digitally or with vascular clamp and sutures. Facilities for cardiopulmonary bypass and auto transfusion/cell saver techniques should be available.

Tracheobronchial Injury[16]

The cervical trachea is usually injured due to neck wounds. Penetrating trauma to central chest may involve major airways like the bronchi and the intrathoracic trachea. There can also be an associated injury to the esophagus. Nonspecific symptoms include cough, dyspnea, voice-change, stridor and frothy bleeding from the wound. Injury distal to the main bronchi may produce pneumothorax or pneumomediastinum and subcutaneous emphysema. There is persistent air leakage and the lung does not re-expand after insertion of chest tube. Patient should be intubated if there is intrabronchial or tracheal bleeding. If this is not possible then tracheostomy should be done. Rigid bronchoscopy is very useful to clear the airways of blood and to diagnose the bronchial or tracheal injury. Anterior tracheal wounds of less than half the tracheal circumference should be primarily closed. Larger anterior and all posterior wounds require debridement prior to repair. Extensive tracheal injury may require resection of two to four rings and reanastomosis with absorbable sutures. The mortality of cervical injury is greater than that of intrathoracic injury. The overall mortality of tracheobronchial injury is around 30%.

Pulmonary Parenchymal Injury[17]

Parenchymal lung injury causes hemorrhage or hemopneumothorax. Ninety percent stab wounds and 70% of low velocity missile wounds are managed by insertion of an intercostal chest tube, analgesics and antibiotics. Thoracotomy is required whenever there is excessive bleeding or massive air leakages which are common with extensive lung laceration or hilar vessel injury in high velocity PCI. The lung tear may be either repairable or resection may be required.

Air embolism is one of the rare but dramatic complication of pulmonary and tracheobronchial injury. It occurs when there is combined airway and vascular injury and air enters the systemic circulation. The clinical manifestations may include confusion, unconsciousness, seizures, and cardiovascular collapse (due to air in the coronary arteries). Treatment consists of cardiopulmonary resuscitation and keeping the head lower than the chest. Rarely, surgery may be required to control the source of air embolism.

Esophageal Injuries[18]

Firearm injuries and stab wounds can cause esophageal injury especially in the cervical region. Associated injury to the adjoining vessels and trachea is fairly common. Clinical presentation includes the occurrence of subcutaneous emphysema, pneumo mediastinum and pleural effusion which may soon turn to empyema formation. Saliva and food particles are noticed in the chest tube drainage fluid. Diagnosis is confirmed by the contrast studies and esophagoscopy. After confirming the diagnosis, an intercostal chest tube should be placed. Treatment administered in the first 24 hours of injury gives the best results. There are a number of surgical techniques devised for this problem - repair of esophagus should be done in early esophageal injury (within 24 hours); in delayed injuries (beyond 24 hours) esophageal bypass procedures are done in view of the marked mediastinal inflammation. The over all mortality is around 15 to 50% depending mainly on the interval between the injury and the treatment.

Great Vessel Injuries[19]

Most of the patients with major thoracic vessel injuries do not reach the hospital alive. Penetrating injuries to the innominate-subclavian system have good prognosis with survival of up to 85%, if there is no cardiac arrest before reaching the hospital. Many of these patients may require immediate thoracotomy for massive bleeding. If patient is stable and diagnosis is not clear, angiography should be done. The surgical approach is done through median sternotomy except in cases of descending thoracic aorta injury when posterolateral thoracotomy is done. Primary repair is possible in majority of patients, otherwise graft interposition or bypass of damaged aorta is done.

MANAGEMENT OF THORACIC TRAUMA

Resuscitation: Practical Aspects

In developed countries, quick transportation of critical trauma patients by helicopters has dramatically changed the outcome of these patients. Similarly in those countries, knowledge of Cardiopulmonary Resuscitation (CPR) by the paramedical personnel and general public has done wonders in saving lives of these patients who otherwise would have died if on site CPR was not done. In most of the developing countries, including in India, such rapid transportation and CPR remain the distant goals.

The CPR of a seriously injured patient should follow the ‘ABC’ principle (Table 172.2).

Management of Blunt Chest Trauma

Most of the blunt chest injuries where heart is not injured, are conservatively managed with pain relief, chest physiotherapy and under water seal intercostal chest tube drainage. Thoracotomy is required in 15 to 20% of blunt chest injuries in the following conditions:

i. *Bleeding:* If after placement of intercostal chest tube, there is immediate drainage of 1500 ml of blood or continuous loss of more than 300 ml/hr for 3 hrs or

TABLE 172.2: The ABC of cardiopulmonary resuscitation

A. *Estabilishing a reliable AIRWAY*
   i. Oropharyngeal airway
   ii. Endotracheal tube
   iii. Tracheostomy
   iv. Bronchoscopy
B. *Restoration of mechanics of BREATHING*
   i. Artificial respiration
   ii. Evacuation of hemopneumothorax
   iii. Stabilize the unstable chest wall
   iv. Mechanical ventilation

C. *Resuscitation of CARDIOVASCULAR system*
   i. IV infusion of fluids—crystalloid, colloid or blood
   ii. Correction of acid-base status and electrolytes
   iii. Ionotropic support
   iv. External or internal cardiac massage
   v. Immediate thoracotomy to stop on-going bleeding

more, it calls for urgent thoracotomy. Similarly, continuous loss of more than 100 ml of blood for two or more consecutive days or continuous brisk bleeding of greater than 100 ml/15 minutes in the chest bottle needs an urgent thoracotomy.

ii. Rupture of bronchus, esophagus, diaphragm or aorta

iii. Cardiac tamponade or cardiac injury.

Mangement of Penetrating Chest injuries

The management includes measures for pain relief, chest physiotherapy, antibiotics and insertion of intercostal chest tube, if indicated.

Surgical intervention in the form of emergency thoracotomy is required later in 15 to 20% of the patients.

i. *Intercostal chest tube drainage:*[20] It is also called underwater seal chest tube drainage. Introduction of Intercostal Drainage (ICD) in the early 20th century was a very major step in the development of thoracic surgery, in the management of chest injuries and empyema. Intercostal drainage is indicated to continuously maintain an atmospheric or subatmospheric pressure in the pleural cavity (Table 172.3).

*Technique***:** Unless, there is tension in pneumothorax, a chest X-ray or ultrasound of chest should be done to decide the exact site for the chest tube.[21] The common sites of insertion are: (i) Apical: 2nd intercostal space in the axilla or infraclavicular area (for pneumothorax), and (ii) basal midaxillary line in 4th or 5th intercostal space (for blood or fluid in the chest cavity).

TABLE 172.3: Common indications for intercostal tube drainage

i. After opening chest— surgery
ii. Chest wall trauma with pleural space disruption
iii. Hemothorax
iv. Empyema
v. Pleural effusion
vi. Pneumothorax—tension or open
vii. Hemopneumthorax

After local anesthesia is infiltrated, an inch long incision is made in the skin and subcutaneous fat and a tract is made through the intercostal muscles along the upper border of rib and through parietal pleura. A chest tube of 28 to 32 F size is inserted in the pleural cavity and attached to a chest bottle or bag (under water seal). Application of negative pressure of 15 to 20 cms water is useful for re-expansion of lung. Chest X-rays should be done frequently to see the progress.

ii. *Management of stable patient:* In stable patients with central PCI, there is little time for investigations, 2-D Echo is a good tool for diagnosing or excluding pericardial tamponade or valvular or septal injuries of heart. Suspected great vessel injury should be confirmed or excluded by angiography. Bronchoscopy is indicated once there is clinical and radiological evidence of the major airway injury. In central penetrating chest injury, CT scan has very little significance but may be required for the associated head and abdominal injuries.

It is important to remember that a stable patient may suddenly deteriorate and will require urgent surgical intervention. A median sternotomy in all cases of central PCI with suspected vascular injury has been advocated without prior investigations because of the possibility of false negative angiograms.

iii. *Management of unstable patient:* Patients who remain serious or deteriorate despite resuscitative measures may require urgent thoracotomy for resuscitation in the emergency department itself.[22] This procedure is beneficial for those patients who arrive in the hospital with some signs of life. A patient who suffers cardiac arrest at the site of accident or en route to the hospital, has a very poor prognosis.

Indications for Thoracotomy (Table 172.4)[23]

Emergency room thoracotomy is required in about 5% cases of blunt chest trauma, more common in PCI

TABLE 172.4: Indications and contraindications for thoracotomy

A. *Emergency room*
   1. Acute pericardial tamponade
   2. Penetrating (stab wounds, gunshot injury) over the precordium.
   3. Cardiac arrest in the presence of fractured sternum or flail over precordium. .
   4. Exsanguinating, uncontrollable, intrathoracic hemorrhage
   5. Failed external cardiac massage requiring internal cardiac massage.
   6. Massive intra abdominal hemorrhage—intrathoracic aorta is cross clamped to control bleeding, this helps in preferential blood supply to brain and heart.

B. *Urgent thoracotomy*
   1. Hemothorax
   2. Large clotted hemothorax—to expand the lung and prevent empyema or fibrothorax
   3. Massive air leakage suggestive of major airway injury or lung parenchymal laceration
   4. Great vessel injury or thoracic inlet vascular injury proved by angiography
   5. Mediastinal traversing injury
   6. Proven esophageal injury
   7. Diaphragmatic injury/ hernia
   8. Chest wall defects
   9. Cardiac septal or valvular injury proved by echo/and cardiac catheterization and angiography
   10. Late cardiac tamponade due to blood or fluid

C. *Delayed thoracotomy*
   1. Clotted hemothorax
   2. Chronic Empyema
   3. Chronic traumatic diaphragmatic hernia
   4. Cardiac septal or valvular Lesions
   5. Missed tracheobronchial injury
   6. Traumatic AV fistula
   7. Delayed aneurysm
   8. Non closing thoracic duct fistula
   9. Infected intrapulmonary hematoma (Lung abcess)
   10. Treatment of various complications of PCI like pneumothorax, hemothorax and pericardial tamponade

D. *Contraindications to thoracotomy*
   1. Small volume hemothorax
   2. Pneumomediastinum
   3. Tension or simple pneumothorax
   4. Multiple pellets in chest wall or lung parenchyma or in a wall of major vessel

patients.[20] The mortality of emergency room thoracotomy is quite high (30 to 70%). Patients who become stable after intial resuscitation but deteriorate during observation, may also require urgent thoracotomy.

Surgical Techniques

The various incisions used for quick exploration of chest consist of the following:

a. *Midsternotomy:* It provides best access to all the chambers of heart and intra-thoracic parts of major vessels like the ascending aorta, the innominate artery, the carotid and the subclavian vessels. It can be extended into neck if required. One needs an electric sternotomy—saw for this procedure. A gigli saw can also do a good job.

b. *Left anterolateral thoracotomy (ALT):* It is an excellent approach in an emergency situation – quick and easy. All one needs is a knife and chest retractor. It is very good for internal cardiac massage. Depending upon the site of hemothorax right or left ALT can be used to drain.

c. *Posterolateral thoracotomy (PLT):* This is an excellent approach for esophageal, tracheobronchial, decending aorta and diaphragm injuries and for decortication in late empyema.

d. *Subxiphoid Pericardiotomy:* A small incision is made below the xiphisternum which is divided in the midline. Pericardium is opened between the two tendons of diaphragm. This approach is very useful in cardiac tamponade as a diagnostic and therapeutic procedure. The only danger is the precipitative massive hemorrhage in case of cardiac injury. This procedure should be done in the operation theater, so if there is need it can be converted into full midsternotomy to tackle the cardiac injury.

e. *Other incisions for chest injuries:* Trans-sternal bilateral thoracotomy, division or partial removal of clavicle and neck incision plus midsternotomy.

Miscellaneous Useful Measures

There are some useful techniques/measures which are of help in the management of chest injury patients:

i. **Autotranfusion:** The technique of auto transfusion of patient's own blood was started at the end of the 19th century for hemoperitoneum for ectopic pregnancy and blunt trauma abdomen. Blood banks were yet to come in that era, so autotransfusion was a life saving measure in those very sick patients.

   For chest injuries, the blood from the pleural cavity is collected in sterile chest bottles or bags and retransfused to the patient like the standard banked blood. This is especially useful in patients with a rare blood group or when there is shortage of that blood in the blood bank.

ii. **Thoracoscopy (Video Assisted Thoracic Surgery—VATS):** This is a useful technique for treating clotted hemothorax, loculated collection of blood, fluid or pus and for treating early empyema. It avoids major thoracotomy in a sick, injured patient.

iii. **Cardio pulmonary Bypass (Intra-aortic Balloon Pump—IABP), LVAD, RVAD:** In a cardiac injury when there is a large tear to a cardiac chamber or damage to a coronary artery, valve or cardiac septum, Cardiopulmonary (CP) bypass is required to treat the problems. Cardiopulmonary bypass is also needed in patients having injury to the ascending aorta or aortic arch or its vessels.

Intra-aortic balloon pump is a device which helps the heart to recover its function after any major cardiac injury leading to low output syndrome. It works on the principle of afterload reduction.

iv. **Extra Corporeal Membrane Oxygenation (ECMO):** If there is marked lung parenchymal injury or a large lung contusion as seen in flail chest, the standard treatment consists of prolonged ventilation. In some of these patients, blood gas reports show low PO_2 in spite of the use of high concentrations of oxygen and other treatments. In such cases, ECMO is a useful measure. In this method, patient's blood is oxygenated using venovenous extracorporeal membrane oxygenator system.

v. **Digital Exploration:** If there is a penetrating wound in the chest wall, one should not do digital exploration in the emergency department. This can lead to serious bleeding requiring emergency thoracotomy for which the place and conditions may not be suitable.

Complications of Chest Trauma

Chest trauma can cause a number of complications as follows:

1. **Lung atelectasis:** Lung atelectasis occurs commonly after blunt chest trauma. In the presence of fracture ribs, the pain causes restriction of respiration leading to alveolar collapse followed by segmental and lobar atelectasis. Retained secretions in the tracheobronchial tree will also lead to atelectasis.
2. **Infection:** Infection is fairly common after chest trauma:
   i. **Bronchopneumonia:** Due to pain after chest trauma, there is retention of secretions causing alveolar and segmental collapse of lung. In addition, the oropharyngeal secretions contain bacteria which migrate downwards in the lungs. Proper control of pain and chest physiotherapy are important for prevention. Appropriate antibiotics and other supportive measures are required for treatment.
   ii. **Empyema**: Hemothorax not properly drained, gets loculated and infected. In PCI, infection from outside can also enter the pleural cavity due to the entry of infected foreign object. Uncommonly, an infected intra-parenchymal hematoma may rupture into the pleural cavity. Treatment of acute empyema consists of proper drainage and antibiotics administration. Chronic empyema requires surgery such as decortication, rib resection with drainage and lung resection with decortication.
3. **Clotted hemothorax:** Hemothorax is common after blunt or penetrating chest injury. If hemothorax is not adequately and timely drained, it becomes a clotted hemothorax. Removal of clots is done through either thoracotomy or VATS. An infected hemothorax can turn to empyema or fibrothorax.
4. **Bronchopleural fistula (BPF):** Injury to a bronchus can lead to a BPF formation, more commonly after PCI than after blunt chest trauma. A BPF leads to partial or total lung collapse and empyema. A small BPF may close with proper ICD. A moderate or large BPF needs surgical treatment—closure of BPF or resection of part of lung containing fistula and decortication for empyema, if present.
5. **Bronchial stenosis:** There can be traumatic rupture of a lobar or main bronchus, usually following blunt chest trauma. If this injury is missed or not treated during the acute stage, bronchial stenosis may occur due to formation of fibrous tissue at the site of rupture. Patient may report with history of breathlessness while radiological investigations may demonstrate lobar or lung collapse on that side. Surgical exploratory thoracotomy is required for patch bronchoplasty or resection of stricture and end to end anastomosis. Results of surgery are generally good.

Lung Transplantation

Sachin Kumar, Ritesh Agarwal

Lung transplantation is an important therapeutic option for selected patients with advanced lung disease.[1] For such patients, transplantation offers the potential for improved quality of life and long-term survival. Currently, lung transplantation as a therapy for end-stage lung disease is limited by the availability of suitable donor organs, resulting in prolonged waiting periods with a substantial number of patients at an increased risk of dying before transplantation.[2,3] Despite advances in donor selection, surgical approach, and more effective immunosuppressive strategies, complications are frequent and result in constraints on long term preservation of graft function and patient survival.[2] Although the present indications and practice of lung transplantation allows only a selected few to benefit, especially in the developing countries such as in India, the future potential of lung transplant surgery is immense, and soon this form of therapy is destined to become a widely applicable treatment for diverse causes of lung diseases.[4-8]

HISTORY OF LUNG TRANSPLANTATION

The vascular experiments in animal models performed by Alexis Carrel at the University of Chicago in the early 1900s laid down the foundations of the surgical techniques for modern solid-organ transplantation.[9,10] In the late 1940s, the Russian surgeon Demikhov performed numerous heart-lung block transplantations without hypothermia or cardiopulmonary bypass in a canine model. By the end of the 1960s, there were three recorded attempts at heart-lung transplantation in humans, one in infant and the other two in adult recipients.[11] The adult patients survived for 8 and 23 days, which demonstrated the ability to breathe spontaneously, that suggested that humans could tolerate denervation.[12]

The advances in immunosuppressive therapy with cyclosporine in renal and heart transplant surgery contributed significantly to the successful introduction of lung transplantation in the early 1980s. In March 1982, the outcome of heart–lung transplantation (HLT) for pulmonary vascular disease in humans was described by the Stanford group.[1,13] After the successful introduction of heart-lung transplantation, single lung transplant was soon performed for interstitial lung disease,[14] followed by en bloc double-lung transplant for emphysema.[15,16] In 1989, bilateral sequential lung transplant (BSLT) was introduced.[17] By 2002, more than 3000 HLT and >20,000 LT operations had been performed worldwide.

GENERAL INDICATIONS

Since 1994, the yearly rate of lung transplants worldwide has remained constant at around 1,300 to 1,500.[18] Selection of lung transplant candidates requires an appreciation of the natural history of lung disease, and understanding of the impact of pre-existing medical co-morbidities on transplant outcomes. Selection is also influenced by the ability of the candidate to sufficiently handle peri and post operative complications associated with lung transplantation. The major indications for lung transplantation are Chronic Obstructive Pulmonary Disease (COPD), Idiopathic Pulmonary Fibrosis (IPF), Cystic Fibrosis (CF), and Primary Pulmonary Hypertension (PPH). Chronic obstructive pulmonary disease together with α-1 antitrypsin deficiency accounts for nearly half of all procedures performed worldwide. Other leading indications include, IPF (19%) and CF (17%). Idiopathic pulmonary arterial hypertension, now accounts for less than 5% of the procedures.[18]

Despite the recent advances, lung transplantation remains risky with a median survival among recipients of only 5 years. Because of the inherent risks involved, it is essential that this option be reserved for a time in the course of disease, when life expectancy is limited and quality of life is unacceptably poor. An individual assessment should be performed for every patient and careful counselling regarding risks and benefits is required. Specialist transplant team members should be consulted to undertake the detailed evaluation.

Selection Criteria for Individual End-Stage Lung Diseases

Disease-specific guidelines for selection and listing of patients have recently been updated and published by the International Society for Heart and Lung Transplantation (ISHLT) (Table 173.1).[19] Once inclusion and exclusion criteria have been met, the appropriate type of lung transplant needs to be considered. Options include heart-lung, single lung, double lung, and live donated lobar transplants. Heart-lung transplants are reserved for patients with Eisenmenger's syndrome with a non-correctable anomaly or a patient with lung disease with severe cardiac dysfunction. Isolated right heart failure due to pulmonary disease is not an indication for a heart-lung transplant, and severe dysfunction of the right heart has been shown to reverse after lung transplant. Double lung transplants are required for CF, bronchiectasis and other pulmonary diseases with secondary infections. Patients with pulmonary hypertension also usually receive a double lung transplant. A single lung transplant is the procedure of choice in most other types of transplant situations, including IPF and COPD.[20]

CONTRAINDICATIONS

Candidates for lung transplantation are thoroughly screened for any comorbidity that might adversely affect the outcome. Suitable candidates should have clinically and physiologically severe lung disease, otherwise they must be in reasonably good health. At most centers, the upper age limit for transplantation is generally set at 65 years.[21-23] Other absolute contraindications include, recent malignancy (other than non-melanoma skin cancer), active infection with the human immunodeficiency virus, hepatitis B or C virus with histologic evidence of significant liver damage, active or recent cigarette smoking, drug or alcohol abuse, severe psychiatric illness, documented and recurrent non-compliance with medical care, and absence of a consistent and reliable social support network.[4,18] Chronic infection with antibiotic-resistant *Pseudomonas*

TABLE 173.1: Disease specific guidelines for selecting candidates for lung transplantation

Chronic Obstructive Pulmonary Disease	BODE index of 7 to 10 or at least one of the following: History of hospitalization for exacerbation associated with acute hypercapnia (PCO_2 exceeding 50 mm Hg); pulmonary hypertension, cor pulmonale or both, despite oxygen therapy; FEV_1 < 20% and either DLCO < 20% or homogenous distribution of emphysema.
Idiopathic Pulmonary Fibrosis	Histologic or radiographic evidence of UIP and any of the following: DLCO < 39% predicted; 10% or greater decrement in FVC during 6 month of follow-up; a decrease in pulse oximetry < 88% during a 6-minute walk test; honeycombing on HRCT (fibrosis score > 2).
Cystic Fibrosis	FEV_1 < 30% of predicted, or rapidly declining lung function if FEV_1 > 30% (females and patients < 18 years of age have a poorer prognosis; consider earlier listing) and/or any of the following: Increasing oxygen requirements; hypercapnia; pulmonary hypertension.
Idiopathic Pulmonary Arterial Hypertension	Persistent NYHA Class III or IV on maximal medical therapy; low (350 m) or declining 6-minute walk test; failing therapy with intravenous epoprostenol or equivalent; cardiac index of < 2 L/min/m^2; right atrial pressure > 15 mm Hg.
Sarcoidosis	NYHA functional Class III or IV and any of the following: Hypoxemia at rest, pulmonary hypertension, elevated right atrial pressure > 15 mm Hg.

Source: Modified from International guidelines for the selection of lung transplant candidates: 2006 update–a consensus report from the pulmonary scientific council of the International Society for Heart and Lung Transplantation. J Heart Lung Transplant 2006;25:745–55.

species, some *Burkholderia* species, *Aspergillus* species or non-tuberculous mycobacteria, is a matter of concern in some patients with CF or other diseases that have a component of bronchiectasis or chronic bronchitis.

WAITING LIST AND ORGAN ALLOCATION

At any given time, a large number of patients are waiting for a lung transplant. Due to the fragility of the lungs in brain-dead patients, only 7 to 22% of multiorgan donors are deemed suitable to become lung donors. Diminishing the donor pool even further, is the wide regional variability in donor organ acceptance rates. Consequently, only 800 to 900 lung transplants are performed yearly in the USA and waiting times for patients listed for a lung transplant continue to increase.[24] Approximately 10% of the patients on the waiting list died before transplantation, but the death rate, while waiting, was much higher for patients with IPF, PPH or CF than for those with COPD or α-1 antitrypsin deficiency emphysema.[3]

Lung allocation was first organized in 1990, under rules designated by the Organ Procurement and Transplantation Network (OPTN), the body which organizes the collection and distribution of solid organ transplants in the United States. The original rules governing lung allotment were simple. Donors were matched to recipients based on 3 criteria: Time spent on the waiting list, ABO blood type, and geographic area.[19] The new lung allocation policy, introduced in May 2005, allocates lungs on the basis of medical urgency and ''net transplant benefit'', defined as the difference between predicted 1-year survival with and without transplantation, so as to minimize the waiting time. Each lung transplant candidate over the age of 12 years would be scored from 0 to 100, with a score of 100 receiving the highest priority. The score was based on wait-list urgency, combined with an estimate of transplant benefit.[25, 26]

Donor Selection

The procurement of acceptable lungs for transplantation is quite difficult. During the first decade after the initial successes of lung transplantation in the early 1980s, the criteria used to select lung donors were quite conservative and stringent.[24] An ideal donor characteristics generally includes, age <55 years, insignificant smoking history, ABO compatibility, acceptable arterial oxygen tension (PaO_2 >300 mm Hg on 100% inspired oxygen with 5 mm Hg of Positive End Expiratory Pressure (PEEP)). There should be a clear chest radiograph and absence of purulent secretions at bronchoscopy. However, while some of these criteria have a sound scientific rationale; the others are controversial, based on small, center-specific reports from the early days of lung transplantation.[24,27] Acceptability criteria for lung donation were recently reviewed in an extensive consensus report from the pulmonary council of the ISHLT. The donor factors that were reviewed from the literature included age, graft ischemic time, blood type ABO compatibility, sex, organ size matching, cause of death, duration of mechanical ventilation, radiographic findings, microbial organisms, arterial blood gases, smoking exposure, and donor diagnoses of malignancy.

Donor Management

Because the process of potential donor identification, brain death certification, family consenting, and organ procurement may take 12 to 24 hours, it is important to focus on maintenance of body temperature via external warming, blood pressure, acid/base status, electrolytes, intravascular volume, and prevention of infection.[28]

Hemodynamic Management

Brainstem death is associated with autonomic crisis, the so called sympathetic storm, whereby a boost of noradrenaline is released in the circulation. This results in acute systemic vasoconstriction, and a rise in systemic vascular resistance that leads to increased pulmonary capillary hydrostatic pressure and deterioration in pulmonary function.[29] The sympathetic discharge is followed by a prolonged period of hypotension leading to a systemic inflammatory syndrome, whereby infiltration of activated neutrophils in the lung contributes to donor lung injury.[30,31] Vasopressors especially low dose vasopressin and iontropes may help stabilize the fluctuations in blood pressure to ensure optimal organ perfusion with the lowest possible myocardial oxygen demand. Patients with pulmonary hypertension undergoing single lung transplantation present particular difficulties, and cardiopulmonary bypass is usually required.[32]

Hormonal Resuscitation

As acute brain death also results in a substantial decrease of several hormones like cortisol, insulin, thyroid and antidiuretic hormone levels, replacement before organ recovery may increase graft viability and early recipient outcome. Administration of high-dose steroids to the donor in the hours after brain death has been advocated, as it is believed to reduce the systemic inflammatory response and thus lung injury.[33]

Postoperative Care

A multidisciplinary team manages the patients in the post-transplant period including, but not limited to, the transplant surgeons, the critical care nursing staff, the transplant coordinators, the transplant pulmonologist, physical and respiratory therapists, nutritionists and infectious disease specialists. Routine early postoperative care includes careful monitoring of vital signs, accurate documentation of intake and output, daily chest-radiographs, and laboratory analysis, including cyclosporine or tacrolimus levels. The serum creatinine must be monitored particularly closely as keeping the patient with relative intravascular volume depletion, together with the use of nephrotoxic immunosuppressive agents, and antibiotics increases the risk for acute kidney injury.[34]

Mechanical Ventilation

A ventilatory strategy with high tidal volumes is potentially harmful and may exacerbate donor lung injury, already triggered by the systemic inflammatory response. The use of low tidal volume ventilation was shown to be beneficial in the ARDS population and is believed to be of help in post-transplant lung due to similar shared pathophysiological mechanisms.[35] Recruitment maneuvers, along with high PEEP are important components of donor ventilatory strategies to prevent atelectasis and achieve adequate oxygenation.[36]

Bronchoscopy

Bronchoscopy should be performed on all potential lung donors to assess for airway damage and visible signs of infection. Examination of the airways is performed in the operating room and again before extubation to evaluate the anastomoses. Regular suctioning of retained secretions through a closed ventilator circuit may be beneficial to improve gas exchange. In patients requiring prolonged mechanical ventilation after transplantation, frequent bronchoscopy may be required to clear secretions, and to obtain microbiologic specimens.[37]

Antimicrobial Therapy

Standard infection prophylaxis are routinely utilized for bacterial, Cytomegalovirus (CMV), *Pneumocystis jirovecii* and *Toxoplasma gondii* infections, and in some centers for fungal infections as well. Patients with cystic fibrosis should undergo periodic preoperative sputum culture analysis for specific antibiotic coverage against *Pseudomonas* species, based on susceptibility data. The incidence of CMV infection after lung transplantation is related to the preoperative CMV status of both the donor (D) and the recipient (R).[38] Transplantation of CMV-seropositive donor lungs transmits a significant viral load to recipients. A discordant CMV status between donor and recipient may result in a higher incidence of acute and chronic rejection, and the mortality rates are even higher compared to patients in whom CMV status is concordant. Therefore, it is recommended to match D and R status.[39] The use of ganciclovir prophylaxis has been shown to eliminate the incidence of primary disease, and to improve the outcome of CMV-disparate lung transplants.[40]

IMMUNOSUPPRESSIVE TREATMENT

The discovery of cyclosporin A (CsA) has been a corner stone for the success of clinical lung transplantation. Lung transplantation performed before the CsA era invariably failed due to inadequate immunosuppression.[41-43] Worldwide, the standard protocol advocates the use of a three-drug regimen for immunosuppression (a calcineurin inhibitor, cell-cycle inhibitor and steroids), with the aim of obtaining additive effects in terms of immune suppression, while limiting drug toxicities. Recently cytolytic therapies such as Campath (anti-CD52), OKT3, daclizumab, basiliximab (anti-CD25) and anti-thymocyte globulin have also been used for this purpose. These therapies are generally initiated within 24 hours of transplantation and are combined with the standard triple-drug regimen. Adverse effects of these immunosuppressive agents include nephrotoxicity, hypertension, hypertrichosis, gastrointestinal disturbances, neurotoxicity, gingival hypertrophy, hyperglycemia and hyperkalemia.[41, 42, 44]

COMPLICATIONS

Lung transplantation has emerged as an effective option in treating a variety of end-stage lung diseases by prolonging life expectancy and by substantially improving quality of life. Unfortunately, the lung transplant recipient is at risk for developing numerous complications that threaten these objectives. Although, early surgical complications and mortality have been minimized due to improvements in lung preservation and surgical techniques, medical complications have become the main rate-limiting factor for long term survival.[45]

Surgical Complications

The airway is the most common location for anastomotic complications after lung transplantation, because of ischemia. Major dehiscence of the bronchial anastomosis was once a major cause of perioperative mortality. Fortunately, refinements in surgical technique, tissue preservation, and immunosuppression have significantly reduced the risk of this life-threatening complication. Focal dehiscence is seen more commonly (in 1 to 6% of cases). Narrowing of the bronchial anastomosis caused by excessive granulation tissue, fibrous stricture or malacia is seen in 5 to 14% of patients.[46] Phrenic nerve injury should be suspected in patients who are difficult to wean from mechanical ventilation, demonstrate paradoxical diaphragmatic movement on examination, and have unexplained persistent atelectasis or an elevated hemidiaphragm on radiographic studies.[47] Pleural complications, especially pneumothorax, air leak and pleural effusion, are common after lung transplantation. Approximately 10% of air leaks are persistent and require prolonged placement of a thoracostomy tube.[48]

Medical Complications

Medical complications of lung transplantation can be categorized into two groups: Pulmonary and non-pulmonary complications (Table 173.2).

TABLE 173.2: Medical complications after lung transplantation

Pulmonary Complications
Complications affecting the allograft(s)
1. Rejection - Acute and chronic
2. Primary graft dysfunction (PGD)
Complications affecting the allograft and native lung
1. Infection
2. Post-transplantation lymphoproliferative disorder (PTLD)
3. Pleural complications
4. Thromboembolic disease
Non pulmonary complications
1. Renal failure
2. Gastrointestinal: Gastroesophageal acid reflux, peptic ulcer disease, ileus, bowel perforation, cholecystitis, appendicitis
3. Endocrine: Diabetes mellitus, hyperlipidemia, obesity, osteoporosis
4. Musculoskeletal: Osteonecrosis, myopathy
5. Neurotoxicity: Tremors, seizures, cerebrovascular accident, blindness, coma
6. Metabolic: Hyperammonemia, electrolyte disturbances
7. Hematologic: Thrombotic microangiopathy, immune hemolysis, cytopenias, hypogammaglobulinemia

Acute Allograft Rejection

Acute lung rejection is defined as perivascular mononuclear cellular infiltrates on histological analysis of lung allograft tissue. The Lung Rejection Study Group (LRSG), under the banner of the ISHLT, has revised a working formulation for grading acute allograft rejection incorporating acute cellular rejection (A-grade), airway inflammation (B-grade), chronic airway rejection, or bronchiolitis obliterans syndrome (BOS C-grade) and chronic vascular rejection (D-grade).[49] Despite the recent development of many new immunosuppressive agents for use in transplantation, acute rejection occurs with much greater frequency in lung allografts when compared to all other solid organ transplants.[50] Why lung allografts are more susceptible to acute rejection is not entirely clear, although it is speculated that lung tissue is more immunogenic. As many as 55% of lung transplant recipients are treated for acute allograft rejection in their first year post transplantation, and only 50% of lung recipients are alive 5 years post transplant.[2] The degree of Human Leukocyte Antigen (HLA) mismatch between donor and recipient, genetic variations in the recipient's innate response, and environmental factors including both the nature and intensity of immunosuppression, as well as local allograft exposures and infections have been identified as risk factors for acute lung rejection.

The precise immune mechanisms and their complex interactions, that ultimately lead to the stimulation of adaptive cellular immunity and lung rejection remain to be fully elucidated. The common pathway of acute cellular rejection involves the recruitment and activation of recipient lymphocytes (predominantly effector T cells) to the lung allograft, which can result in allograft injury and loss of function. In addition, some lung transplant recipients appear to mount a humoral response to the allograft after transplantation.[51,52] Most evidence suggests that this humoral response occurs to donor Major Histocompatibility Complex (MHC) antigens, although other endothelial or epithelial antigens expressed in the lung may become antibody targets as well.

The diagnosis of acute cellular rejection relies on the identification of lymphocytic perivascular or bronchiolar infiltrates in lung tissue. When symptomatic, acute rejection presents with dyspnea, cough or sputum production. However, in view of non-specific clinical symptoms and the poor specificity of non-invasive studies, bronchoscopy with transbronchial biopsies is the most important modality in the diagnosis of acute allograft rejection, and should be considered in any lung transplant recipient with allograft dysfunction. It allows acute rejection to be distinguished from other potential etiologies of allograft dysfunction, such as airway stenosis or infection and routinely includes Bronchoalveolar Lavage (BAL) with cultures and transbronchial biopsies for histopathological analysis. A common schedule consists of bronchoscopy at 1 month, 3 months, 6 months and then annually. The main rationale for surveillance biopsies includes the occurrence of clinically silent acute rejection. Multiple studies demonstrate that acute rejection is associated with the development of chronic airflow obstruction as well as increased risk for BOS.[50]

Treatment of acute lung allograft rejection consists of pulse methylprednisolone intravenously for about three doses followed by an oral prednisone taper. Several studies have found tacrolimus useful for treatment of persistent acute rejection.[53,54] Other rescue therapeutic modalities include pulse treatments with a polyclonal Antithymocyte Globulin (ATG), anti-interleukin-2-receptor antagonists, or muromonab-CD3 (OKT3), and recently alemtuzumab, an anti-CD52 monoclonal antibody. Plasmapheresis is the mainstay for antibody removal from the circulation with humoral rejection in lung transplant recipients and in patients with pulmonary capillaritis unresponsive to steroids.[55]

Chronic Allograft Rejection: Bronchiolitis Obliterans Syndrome (BOS)

Bronchiolitis obliterans syndrome remains the major limiting factor to long-term survival after lung transplantation, and is the leading cause of death after the first year. Approximately 30% and 75% of patients develop BOS by 2.5 and 10 years after transplantation, respectively.[18] The histological pathognomonic lesion of chronic rejection is, Obliterative Bronchiolitis (OB) characterized by an inflammatory/fibrotic process affecting the small non-cartilagenous airways (membranous and respiratory bronchioles) causing partial or complete luminal occlusion. Bronchilolitis obliterans syndrome affects all lung transplant recipients irrespective of donor and recipient's characteristics. The time between transplantation and BOS onset, ranges from a few months to several years. The presentation may be acute and imitate a respiratory infection. In most patients, however, BOS is an asymptomatic process that produces an insidious decline in lung function. As the disease progresses, permanent airway colonization with pathogens such as *Pseudomonas aeruginosa* and *Aspergillus fumigatus* frequently develops.[51]

Classically, BOS is considered to be the end-stage consequence of repeated alloimmune-dependent and -independent mechanisms acting alone, or in combination to the lung allograft.[56] There are a number of factors that are strongly correlated with the development of OB. These include the frequency of acute rejection, particularly in the first three months after transplant. Also, the finding on transbronchial biopsy of a lymphocytic bronchitis or bronchiolitis is strongly associated with the subsequent development of OB. The occurrence of CMV infection or other significant pneumonias does not seem so clearly associated with the development of OB.[57]

The diagnosis of BOS is defined by a sustained (≥ 3 weeks) decline in the FEV_1 provided alternative causes of pulmonary dysfunction (e.g. anastomotic stricture/complications, infection, acute rejection and recurrent or progressive native disease) have been excluded.[58] The syndrome was classified according to the degree of FEV_1 reduction.[58]

Treatment options for BOS generally remain disappointing. Augmentation of immunosuppression or changing immunosuppressive medications within therapeutic classes has been a mainstay of therapy. In light of limited availability of donor lungs, the role of re-transplantation remains controversial.

Primary Graft Dysfunction (PGD)

Primary Graft Dysfunction (also known as primary graft failure, severe ischemia-reperfusion injury or re-implantation response) is a severe, acute lung injury syndrome after lung transplantation, that is characterized by diffuse radiographic infiltrates in the allograft and increased alveolar–arterial oxygen gradient.[59,60] Primary graft dysfunction affects 10 to 25% of all lung transplants and is a leading cause of early morbidity and mortality.[18,61,62] Primary graft dysfunction likely represents a form of ischemia-reperfusion lung injury occurring within the first three days of lung transplantation in a variety of clinical presentations. In 2004, the International Society for Heart and Lung Transplantation (ISHLT) working group on PGD after lung transplantation developed a classification system upon which to grade the severity of allograft dysfunction based on the degree of hypoxemia ($PaO_2:FiO_2$ ratio) and chest radiograph appearance.[62]

On lung biopsy, the histological pattern is one of acute lung injury with reactive type II pneumocytes.[63] Additional histological findings in severe cases can include hyaline membranes along the alveolar ducts, neutrophil infiltration and detachment of endothelial cells from the basement membrane. Many steps involved in the lung transplant procedure contribute to the development of PGD, including changes in donor homeostasis related to brain death prior to harvesting, aerobic hypothermic preservation during organ transit and intraoperative organ reperfusion. Central to this process is ischemia-reperfusion injury with the generation of harmful and damaging Reactive Oxygen Species (ROS). Donor acquired risk factors, that potentially contribute to the development of PGD include prolonged mechanical ventilation, aspiration pneumonitis/pneumonia or ventilator-associated pneumonia, trauma, and hemodynamic instability, and the systemic inflammatory response following brain death. Elevated recipient pulmonary artery pressures are also associated with increased risk of PGD.[64] Studies on the impact of prolonged graft ischemic times have yielded conflicting results.[65]

There is no specific treatment for PGD that has proven efficacious. Several principles underlying the supportive care of patients who have acute respiratory distress syndrome may be helpful. However conventional mechanical ventilation using low tidal-volume strategies to reduce the risk of ventilator-induced lung injury is recommended. Although, inhaled nitric oxide or prostacyclin may improve oxygenation transiently, studies have not shown clinically significant benefits.[66] PGD is a major cause of perioperative death, with studies reporting mortality rates over 60%. These patients require prolonged duration of mechanical ventilation and extended hospital stay. In addition, patients who have PGD, who recover from respiratory failure and survive beyond the first transplant year continue to be at higher risk for death and on average have poorer functional outcomes, than patients who do not have PGD.[67,68]

Malignancy

The incidence of malignancy is higher in patients who have undergone lung transplant than in those who have undergone other solid-organ transplants.[69] The prevalence of malignancy in patients who have undergone lung transplant is reported to be 3.7% in 1-year survivors and 25% in 10-year survivors. Beyond the first year, malignancy accounts for 9.3% of deaths.[45] Post-Transplantation Lymphoproliferative Disorder (PTLD) being the most common cancer in the first 2 years after transplantation and skin cancers the most common malignant after the second year.[69,70] PTLD comprises a spectrum of disorders that arise in post-transplant patients that are due to abnormal lymphoid proliferation.[71] The reported incidence of PTLD ranges from 2 to 8%.[72] The pathogenesis of PTLD is related to reactivation of the Epstein-Barr Virus (EBV) and usually involves B cells (76 to 95%).[73] Clinically, early cases of PTLD generally present with constitutional symptoms, infectious mononucleosis, like illness and thoracic manifestations, which may include pulmonary nodule(s) or infiltrate(s) usually located in the allograft, and at times mediastinal lymphadenopathy.[74,75] Immunotherapy with rituximab has been used with success for PTLD in solid-organ transplants and in lung transplants.[76,77]

Bronchogenic Carcinoma

Lung transplant recipients are at risk for bronchogenic carcinoma due to several factors, including older age, prior smoking exposure, underlying chronic obstructive or fibrotic pulmonary disease, and the effects of immunosuppressive regimen.[78-80] Bronchogenic carcinoma diagnosed after lung transplantation has a very aggressive course with a poor prognosis. The incidence of bronchogenic carcinoma after lung transplantation ranges between 2 and 4% in recipients with COPD and IPF.[78, 80]

Thromboembolic Disease

Venous thromboembolism disease, which includes deep venous thrombosis and pulmonary embolism, has an increased incidence in lung transplant recipients, with a reported incidence of 8.6 to 29%.[81-84] The etiology for the increased incidence of thromboembolism in patients who have undergone lung transplant is unclear but risk factors may be advanced age, diabetes, concomitant pneumonia, greater immobility, and a higher incidence of indwelling catheter placement.[85, 86] Treatment consists of standard heparin followed by warfarin for long-term anticoagulation.

Infectious Complications

Infectious complications following lung transplantation are associated with significant morbidity and mortality.[87] The pulmonary allograft is the most common infection site.[88] Distinctive infectious complications such as *Mycobacteria*, *Stenotrophomonas*, *Burkholderia*, and *Pseudomonas* have unique clinical features that impact the post-transplant survival and medical management of these complex patients.[89] The highest risk of pneumonia is during the first month after lung transplantation and this risk reduces after 6 months and of those in which an etiology was found (67%), *Pseudomonas* is the most common (25%) isolated organism.[89,90] The incidence of *P. aeruginosa* in the post-transplant lungs is significantly higher in patients who underwent transplant for CF compared with other indications (60.3% vs 38.2%).[91] Colonization with pan-resistant bacteria was associated with a slightly decreased survival following lung transplantation. Later in the time course, after lung transplantation, the frequency of *P. aeruginosa* colonization in airways increases and can be associated with chronic graft rejection, the BOS.

Burkholderia cepacia complex may cause multi- or pan-resistant invasive infections in patients with CF, and is associated with a pre-transplant mortality of up to 50%. However, the virulence factors of *B. cepacia* complex are still poorly understood and differ between the strains of each genomovar. Whether colonization with *B. cepacia* is an absolute contraindication to transplant remains controversial.[92] Infection with *M. tuberculosis* may occur due to reactivation, occult disease in the remaining native lung after single lung transplantation, transmission by transplantation or nosocomial infection.[89,93] Infections with non-tuberculous mycobacteria are infrequent.[94]

Cytomegalovirus is one of the most important pathogens after lung transplantation. Transplantation of CMV-seropositive donor lungs transmits a significant viral load to recipients.[95] Recipients with evidence of previous/latent CMV infection (seropositive recipients) are at risk, while seronegative recipients transplanted with a seropositive pulmonary graft (D+R-) are at highest risk of developing CMV infection and disease after lung transplantation (primary infection).[96] The incidence is reported to range from 30 to 86%, with an associated mortality range of 2 to 12%.[38,95,97,98] With prophylactic treatment, the presentation of CMV infection occurs later after transplantation. Without prophylaxis, the symptoms of CMV reactivation occur typically between the first and fourth month after transplantation. Newer quantitative molecular techniques for detection of CMV antigens allows for early and more sensitive detection of active viral replication, and may correlate with CMV disease, which is defined as symptomatic end-organ involvement attributable to active infection. Quantitative PCR, hybrid capture assays and the semi-quantitative pp65-antigenemia assay, have shown to be effective in diagnosis of CMV infection, however quantitative methods are most predictive of disease severity.[99] The most serious manifestation of CMV disease is CMV pneumonitis, a relatively common manifestation of either primary or reactivation of chronic pulmonary viral infection in immunocompromised hosts. Commonly used protocols vary from 90 days of prophylaxis with IV ganciclovir in high-risk recipients only (D+R-), to indefinite prophylaxis with CMV immunoglobulin, followed by daily oral valaciclovir in all transplant recipients.[100,101] Beside direct effects of CMV disease leading to organ damage, CMV provokes additional alteration of the immune system, referred to as indirect effects of CMV infection such as acute and chronic rejection.[96] The Gamma herpes viridae including HHV 8 and EBV, are oncogenic viruses. HHV 8 causes Kaposi sarcoma. EBV is strongly associated with PTLD.[77]

Fungal infections occur in 15 to 35% recipients after lung transplantation. *Aspergillus* species, together with *Candida*, are responsible for early fungal colonization of the airways.[102] The mortality rate of fungal infections can be over 80%.[103] The diagnosis of invasive aspergillosis is difficult. The airways of up to 55% of lung transplant recipients can be colonized with *Aspergillus* species. Nodular opacities and areas of consolidation observed on computer tomogram that may indicate invasive pulmonary *Aspergillus* infections may also represent other diagnoses.[102,104] Other emerging rapid laboratory methods are diagnostic tests for 1/3-beta-D-Glucan. Invasive infections with *Candida* species include candidemia, mediastinitis and necrotic infections of the anastomosis.[105,106] Zygomycosis as an invasive fungal infection with saprophytic fungi, including *Rhizopus*, *Rhizomucor*, *Mucor* and *Absidia* are also seen infrequently. The overall mortality is approximately 50%.[96]

Renal Failure

Renal dysfunction is one of the most common long-term complications of lung transplant, occurring in 25.5% of cases at 1 year after transplant and 37.8 at 5 years after transplant.[2] The most common cause of renal failure is due to calcineurin inhibitor nephrotoxicity. Other factors are hypertension, hyperlipidemia, and diabetes. Additional insults to the kidney at the time of transplant due to hypotension, hypoperfusion and aortic cross-clamp, and aggressive diuresis contribute to the assault.[107-109] Management of kidney disease include lowering the levels of calcineurin inhibitor if the lower levels of immunosuppression can be tolerated. Associated comorbidities such as hypertension, diabetes and hyperlipidemia should be aggressively treated. The progression of chronic renal failure ultimately leads to renal replacement therapy in the form of dialysis or renal transplantation.[73]

Diabetes Mellitus

The development of diabetes is a relatively common in patients who have undergone lung transplant, with incidence of 33.5% at 5 years after transplant.[2] Risk factors leading to the development of diabetes are due to glucocorticoid use and calcineurin inhibitor use, with tacrolimus having a much greater likelihood than cyclosporine of inducing diabetes.[110] Other risk factors include older age of recipients, obesity, and frequent acute rejection requiring high dose steroids. Guidelines for treatment of diabetes for solid organ transplants recommend intervention, when patients have fasting glucose levels greater than 126 mg/dl and hemoglobin A1C levels greater than 6.5%.[111]

Cardiovascular Complications

Cardiovascular cause of death accounts for less than 5.3% of deaths in patients who survive longer than 1 year.[2] Hypertension, hyperlipidemia, diabetes and renal disease contribute to the heightened risk. Use of statin may lower the risks associated with these cardiovascular comorbidities in addition to lowering the risk of rejection and BOS.[73]

Osteoporosis

Osteoporotic bone loss appears to be accelerated in the first 3 to 6 months after transplant for all solid-organ transplants, as measured by decreases in BMD scores.[112-114] Within the first year of lung transplant, the post-lung transplant fracture rate ranges from 6 to 18% and a loss in BMD of 4 to 12% is reported.[115] Estrogen and hormone replacement therapy, in combination with calcium and vitamin D supplementation and bisphosphonates, have been shown to prevent decreases in BMD.[73]

Neurologic Complications

The majority of complications were due to calcineurin inhibitor toxicity or infections.[73] Manifestations of calcineurin inhibitor toxicity include confusion, tremor, paresthesias of hand and feet seizure, blindness and encephalopathy.

OUTCOMES

Lung transplants are expensive procedures and are associated with a continued cost of care that involves not only the immunosuppressive treatments but also the monitoring of lung function and diagnostic procedures. With careful candidate selection using current criteria, overall results of LT have improved over the decades. The current 1-, 5- and 10-year unadjusted survival outcomes are 79%, 52% and 29%, respectively.[18] Another observation that possibly impacts on survival is the type of transplant performed. In the recent analysis of data from the ISHLT registry, there appears to be a small survival advantage for patients who have received DLT compared with SLT procedures.[18] Despite improvement in the peri-operative survival, over the long-term the slope of the survival curve continues to show the same slow attrition rate reflecting the problem of chronic rejection, for which there remains no effective therapy.

Pulmonary Function and Gas Exchange

When performed in patients with obstructive or restrictive lung disease, both single-lung and bilateral transplantation dramatically improve lung function. The peak effect of transplantation on lung function is typically achieved within three to six months. Exercise capacity improves sufficiently to allow the majority of transplant recipients to resume an active and unencumbered lifestyle.

Quality of Life

Despite the availability of highly reproducible tools to assess the quality of life, information on the effect of lung transplantation on this outcome measure is limited.[116] Important improvements in QOL are reported after lung transplantation. Recent studies show that heart and lung transplant patients benefit from the transplant procedure with respect to HRQOL improvements for at least 5 years post-transplant; however, their trajectories during this time interval differ.[117] Lung transplant recipients generally were satisfied with their decision to have undergone transplantation.[118]

THE FUTURE OF LUNG TRANSPLANTATION

Lung transplantation has reached its current clinical plateau largely through refinements in the selection of patients, operative techniques and postoperative care. Two major hurdles must be overcome to increase the applicability of lung transplantation and improve long-term results: The supply of donor organs must be increased to meet the demand and chronic rejection must be more effectively prevented. There are a number of emerging therapies like stem cell therapy and xenotransplantation that may offer alternatives to human organ transplantation. However, as of now, the supporting data is too meagre to recommend them as a standard of care rather than experimental therapy.

LUNG TRANSPLANTATION IN INDIA

The burden of chronic respiratory diseases in India is on the rise, accounting for nearly 1 in 10 deaths. Improved access to healthcare and better imaging modalities have led to an increase in the diagnosis of advanced chronic lung diseases like IPF and pulmonary artery hypertension in India. For these end-stage lung diseases, lung transplantation is an effective and established treatment option in the developed world. However, this expensive form of treatment coupled with lack of infrastructure and the expertise involved, makes lung transplantation programmes in India currently out of reach of most of the population. The first heart-lung transplant in India was performed on May 3, 1999 and subsequently, two more patients have undergone this procedure. The initial experience is encouraging and heralds a new era of thoracic organ transplantation in India.[119]

SUMMARY

Lung transplantation has emerged as a viable therapeutic option in treating a variety of end-stage lung diseases by prolonging life expectancy and by substantially improving quality of life. Since the advent of the first lung transplant there has been substantial progress made in surgical techniques, lung preservation, immunosuppression and management of infections thereby improving the short-term mortality. However, there are numerous problems and complications that limit the long-term success of this vital treatment modality. Chronic allograft rejection in the form of BOS continues to be the common cause of morbidity and mortality and, threatens to shorten the long term survival of the lung transplant recipients. There is still a scope of much research in transplantation immunobiology so as to cross this hurdle before lung transplantation fulfils its potential as an effective and definitive treatment option for patients with advanced lung disease.
